# DSL ENGINEERING

## **Part I**

# **DSL Design**

## *Core Design Dimensions*

This part of the book has been written together with Eelco Visser of TU Delft. Reach him via [e.visser@tudelft.nl](mailto:e.visser@tudelft.nl).

DSLs are languages with high expressivity for a specific, narrow problem domain. They are a powerful tool for software engineering, because they can be tailor-made for a specific class of problems. However, because of the large degree of freedom in designing DSLs, and because they are supposed to cover the right domain, completely, and at the right abstraction level, DSL design is also hard. In this chapter we present a framework for describing and characterizing external domain specific languages. We identify eight design dimensions that span the space within which DSLs are designed: expressivity, coverage, semantics, separation of concerns, completeness, large-scale model structure, language modularization and syntax. We illustrate the design alternatives along each of these dimensions with examples from our case studies.

THIS PART OF THE BOOK presents a conceptual framework for the description of DSL design, based on eight dimensions: expressivity, coverage, semantics and execution, separation of concerns, structuring programs, language modularity, and concrete syntax. These dimensions provide a vocabulary for describing and comparing the design of existing DSLs. While the chapter does not contain a complete methodology for designing new DSLs, the framework does highlight the options designers should consider. We also describe drivers, or forces, that lead to using one design alternative over another one.

### 1.1 Programs, Languages, Domains

Domain-specific languages live in the realm of *programs*, *languages*, and *domains*. We are primarily interested in *computation*. So, let's first consider the relation between programs and languages. Let's define  $P$  to be the set of all programs. A *program*  $p$  in  $P$  is the Platonic representation of some *effective computation* that runs on a universal computer. That is, we assume that  $P$  represents the canonical semantic model of all programs and includes all possible hardware on which programs may run. A *language*  $L$  defines a structure and notation for *expressing* or *encoding* programs. Thus, a program  $p$  in  $P$  may have an expression in  $L$ , which we will denote  $p_L$ . Note that  $p_{L_1}$  and  $p_{L_2}$  are representations of a single semantic (platonic) program in the languages  $L_1$  and  $L_2$ . There may be multiple ways to express the same program in a language  $L$ . A language is a *finitely generated* set of program encodings. That is, there must be a finite description that generates all program expressions in the language. As a result, it may not be possible to define all programs in some language  $L$ . We denote as  $P_L$  the subset of  $P$  that can be expressed in  $L$ . A translation  $T$  between languages  $L_1$  and  $L_2$  maps programs from their  $L_1$  encoding to their  $L_2$  encoding, i.e.  $T(p_{L_1}) = p_{L_2}$ .

**Pension Plans:** The pension language can be used to effectively represent pension calculations, but cannot be used to express general purpose enterprise software ◀

**NOW, WHAT ARE DOMAINS?** There are essentially two approaches to characterize domains. First, domains are often considered as a body of knowledge in the real world, i.e. outside the realm of software. From this *deductive* or *top-down* perspective, a domain  $D$  is a body of knowledge for which we want to provide some form of software support. We define  $P_D$  the subset of programs in  $P$  that implement computations in  $D$ , e.g. 'this program implements a fountain algorithm'.

**Pension Plans:** The pensions domain has been defined this way. The customer had been working in the field of old age pensions for decades and had a very detailed understanding of what the pension domain entails. That knowledge was mainly contained in the heads of pension experts, in pension plan requirements documents, and, to some extent, encoded in the source of existing software. ◀

In the *inductive* or *bottom-up* approach we define a domain in terms of existing software. That is, a domain  $D$  is identified as a subset  $P_D$  of  $P$ , i.e. a set of programs with common characteristics or similar purpose. Often, such domains do not exist outside the realm of software.

Figure 1.1: Programs, Languages, Domains

A special case of the inductive approach is where we define a domain as a subset of programs of a specific  $P_L$  instead of the more general set  $P$ . In this special case we can often clearly identify the commonality between programs in the domain, in the form of their consistent use of a set of domain-specific patterns or idioms.

**Embedded C:** The extensions to the C programming language are defined bottom-up. Based on idioms commonly used when using C for a given class of problems, linguistic abstractions have been defined that provide a "shorthand" for those idioms. These linguistic abstractions form the basis of the language extensions. ◀

The above example can be considered relatively general — the domain of embedded software development is relatively broad. In contrast, a domain may also be very specific.

**Refrigerators:** The cooling DSL is tailored specifically to expressing refrigerator cooling programs for a very specific organization. No claim is made for widespread usefulness of the DSL. However, it perfectly fits into the way cooling algorithms are described and implemented in that particular organization. ◀

Whether we take the deductive or inductive route, we can ultimately identify a domain  $D$  by a set of programs  $P_D$ . There can be multiple languages in which we can express  $P_D$  programs. Possibly,  $P_D$  can only be partially expressed in a language  $L$  (Figure 1.1). A *domain-specific language*  $L_D$  for  $D$  is a language that is *specialized* to encoding  $P_D$  programs. That is,  $L_D$  is more efficient in some respect in representing  $P_D$  programs. Typically, such a language is *smaller* in the sense that  $P_{L_D}$  is a strict subset of  $P_L$  for a less specialized language  $L$ .

THE CRUCIAL DIFFERENCE BETWEEN LANGUAGES AND DOMAINS is that the former are finitely generated, but that the latter are arbitrary sets of programs the membership of which is determined by a human oracle. This difference defines the difficulty of DSL design: finding regularity in a non-regular domain and capturing it in a language. The resulting DSL represents an explanation or interpretation of the domain, and often requires trade-offs by under- or over-approximation (Figure 1.2).

### 1.1.1 Programs as Trees of Elements

Programs are represented in two ways: concrete syntax and abstract syntax. A language definition includes the concrete and the abstract syntax, as well as rules for mapping one to the other. *Parser-based* systems map the concrete syntax to the abstract syntax. Users interact with a stream of characters, and a parser derives the abstract syntax by using a grammar and mapping rules. *Projectional* editors go the other

Figure 1.2: Languages  $L_1$  and  $L_2$  under-approximate and over-approximate domain  $D$ .

Users use the concrete syntax as they write or change programs. The abstract syntax is a data structure that contains all the data expressed with the concrete syntax, but without the notational details. The abstract syntax is used for analysis and downstream processing of programs.

way round. User editing gestures directly change the abstract syntax, the concrete syntax being a mere projection that looks and feels like text if a textual projection is used. SDF and Xtext are parser-based, MPS is projectional.

The abstract syntax of programs are primarily trees of program *elements*. Every element (except the root) is contained by exactly one parent element. Syntactic nesting of the concrete syntax corresponds to a parent-child relationship in the abstract syntax. There may also be any number of non-containing cross-references between elements, established either directly during editing (in projectional systems) or by a name resolution (or *linking*) phase that follows parsing and tree construction.

A program may be composed from several program *fragments*. A fragment is a standalone tree.  $E_f$  is the set of program elements in a fragment  $f$ .

A LANGUAGE  $l$  defines a set of language concepts  $C_l$  and their relationships<sup>1</sup>. In a fragment, each element  $e$  is an instance of a concept  $c$  defined in some language  $l$ .

**Embedded C:** In  $C$ , the statement `int x = 3;` is an instance of the *LocalVariableDeclaration*. `int` is an instance of *IntType*, and the `3` is an instance of *NumberLiteral*. ◀

We define the *concept-of* function  $co$  to return the concept of which a program element is an instance:  $co \Rightarrow element \rightarrow concept$ . Similarly we define the *language-of* function  $lo$  to return the language in which a given concept is defined:  $lo \Rightarrow concept \rightarrow language$ . Finally, we define a *fragment-of* function  $fo$  that returns the fragment that contains a given program element:  $fo \Rightarrow element \rightarrow fragment$ .

We also define the following sets of relations between program elements.  $Cdn_f$  is the set of parent-child relationships in a fragment  $f$ . Each  $c \in C$  has the properties *parent* and *child*.

**Embedded C:** In `int x = 3;` the local variable declaration is the parent of the type and the init expression `3`. The concept *LocalVariableDeclaration* defines the containment relationships *type* and *init*, respectively. ◀

$Refs_f$  is the set of non-containing cross-references between program elements in a fragment  $f$ . Each reference  $r$  in  $Refs_f$  has the properties *from* and *to*, which refer to the two ends of the reference relationship.

**Embedded C:** For example, in the `x = 10;` assignment, `x` is a reference to a variable of that name, for example, the one declared in the previous example paragraph. The concept *LocalVariableRef* has a non-containing reference relationship *var* that points to the

While concrete syntax modularization and composition can be a challenge (as discussed in Section 1.8.5), we will illustrate most language design concerns based on the abstract syntax.

<sup>1</sup> We use the term concept to refer to concrete syntax, abstract syntax plus the associated type system rules and constraints as well as some definition of its semantics.

respective variable. ◀

Finally, we define an inheritance relationship that applies the Liskov Substitution Principle to language concepts. A concept  $c_{sub}$  that extends another concept  $c_{super}$  can be used in places where an instance of  $c_{super}$  is expected.  $Inh_l$  is the set of inheritance relationships for a language  $l$ . Each  $i \in Inh_l$  has the properties *super* and *sub*.

**Embedded C:** The *LocalVariableDeclaration* introduced above extends the concept *Statement*. This way, a local variable declaration can be used wherever a statement is expected, for example, in the body of a function, which contains a list of statements. ◀

An important concept in LMR&C is the notion of independence. An *independent language* does not depend on other languages. An independent language  $l$  can be defined as a language for which the following hold:

$$\forall r \in Refs_l \mid lo(r.to) = lo(r.from) = l \quad (1.1)$$

$$\forall s \in Inh_l \mid lo(s.super) = lo(s.sub) = l \quad (1.2)$$

$$\forall c \in Cdn_l \mid lo(c.parent) = lo(c.child) = l \quad (1.3)$$

An *independent fragment* is one where all non-containing cross-references stay within the fragment (1.4). By definition, an independent fragment has to be expressed with an independent language (1.5).

$$\forall r \in Refs_f \mid fo(r.to) = fo(r.from) = f \quad (1.4)$$

$$\forall e \in E_f \mid lo(co(e)) = l \quad (1.5)$$

**Refrigerators:** The hardware definition language is independent, as are fragments that use this language. In contrast, the cooling algorithm language is dependent. The *BuildingBlockRef* concept declares a reference to the *BuildingBlock* concept defined in the hardware language. Consequently, if a cooling program refers to a hardware setup using an instance of *BuildingBlockRef*, the fragment becomes dependent on the hardware definition fragment that contains the referenced building block. ◀

We also distinguish *homogeneous* and *heterogeneous* fragments. A homogeneous fragment is one where all elements are expressed with the same language:

$$\forall e \in E_f \mid lo(e) = l \quad (1.6)$$

$$\forall c \in Cdn_f \mid lo(c.parent) = lo(c.child) = l \quad (1.7)$$

**Embedded C:** A program written in plain C is homogeneous. All program elements are instances of the C language. Using the

Figure 1.3: Domain hierarchy. Domains with higher index are called subdomains of domains with a lower index ( $D_1$  is a subdomain of  $D_0$ ). We use just  $D$  to refer to the current domain, and  $D_{+1}$  and  $D_{-1}$  to refer to the relatively more specific and more general ones.

statemachine language extension allows us to embed state machines in C programs. This makes the respective fragment heterogeneous. ◀

### 1.1.2 Domain Hierarchy

The subsetting of domains naturally gives rise to a hierarchy of domains (Fig. 1.3). At the bottom we find the most general domain  $D_0$ . It is the domain of all possible programs  $P$ . Domains  $D_n$ , with  $n > 0$ , represent progressively more specialized domains, where the set of possible programs is a subset of those in  $D_{n-1}$  (abbreviated as  $D_{-1}$ ). We call  $D_{+1}$  a subdomain of  $D$ . For example,  $D_{1,1}$  could be the domain of embedded software, and  $D_{1,2}$  could be the domain of enterprise software. The progressive specialization can be continued ad-infinitum in principle. For example,  $D_{2,1,1}$  and  $D_{2,1,2}$  are further subdomains of  $D_{1,1}$ :  $D_{2,1,1}$  could be automotive embedded software and  $D_{2,1,2}$  could be avionics software. At the top of the hierarchy we find singleton domains that consist of a single program (a non-interesting boundary case). Languages are typically designed for a particular  $D$ . Languages for  $D_0$  are called general-purpose languages. Languages for  $D_n$  with  $n > 0$  become more domain-specific for growing  $n$ .

**Embedded C:** The C base language is defined for  $D_0$ . Extensions for tasks, state machines or components can be argued to be specific to embedded systems, making those sit in  $D_{1,1}$ . Progressive specialization is possible; for example, a language for controlling small lego robots sits on top of state machines and tasks. It could be allocated to  $D_{2,1,1}$ . ◀

### 1.1.3 Model Purpose

We have said earlier that there can be several languages for the same domain. Deciding which concepts should go into a particular language for  $D$ , and at which level of abstraction or detail, is not always obvious. The basis for the decision is to consider the *model purpose*. Models, and hence the languages to express them, are intended for a specific

purpose. Examples of model purpose include automatic derivation of a  $D_{-1}$  program, formal analysis and model checking or platform independent specification of functionality<sup>2</sup>. The same domain concepts can often be abstracted in different ways, for different purposes. When defining a DSL, we have to identify the different purposes required, and then decide whether we can create one DSL that fits all purposes, or create a DSL for each purpose.

**Embedded C:** The model purpose is the generation of an efficient low-level C implementation of the system, while at the same time providing software developers with meaningful abstractions. Since *efficient C* code has to be generated, certain abstractions, such as dynamically growing lists or runtime polymorphic dispatch are not supported. The state machines in the statemachines language have an additional model purpose: model checking, i.e. proofing certain properties about the state machines (e.g. proofing that a certain state is definitely going to be reached after some event occurs). To enable this, actions used in the state machines are further limited. ◀

**Refrigerators:** The model purpose is the generation of efficient implementation code for various different target platforms. A secondary purpose is enabling domain experts to express the algorithms and experiment with them using simulations and tests. The DSL is not expected to be used to visualize the actual refrigerator device or for sales or marketing purposes. ◀

**Pension Plans:** The model purpose of the pension DSL is to enable insurance mathematicians and pension plan developers (who are not programmers) to define complete pension plans, and to allow them to check their own work for correctness using various forms of tests. A secondary purpose is the generation of the complete calculation engine for the computing center and the website. ◀

#### 1.1.4 Parsing vs. Projection

There are two main approaches for implementing external DSLs. The traditional approach is parser-based. A grammar specifies the sequence of tokens and words that make up a structurally valid program. A parser is generated from this grammar. A parser is a program that recognizes valid programs in their textual form and creates an abstract syntax tree or graph. Analysis tools or generators work with this abstract syntax tree. Users enter programs using the concrete syntax (i.e. character sequences) and programs are also stored in this way. Example tools in this category include Spoofox and Xtext.

<sup>2</sup> Communication among humans could be another model purpose. However, we consider languages used only for human-to-human communication outside the scope of this book, because they don't have to be formally defined to achieve their goal.

Projectional editors (also known as structured editors) work without parsers. Editing actions directly modify the abstract syntax tree. Projection rules then render a textual (or other) representation of the program. Users read and write programs through this projected notation. Programs are stored as abstract syntax trees, usually as XML. As in parser-based systems, backend tools operate on the abstract syntax tree. Projectional editing is well known from graphical editors, virtually all of them use this approach. However, they can also be used for textual syntax. Example tools in this category include the Intentional Domain Workbench (<http://intentsoft.com>) and JetBrains MPS.

In this section, we do not discuss the relative advantages and drawbacks of parser-based vs. projectional editors in any detail (we do discuss the tradeoffs in the chapter on language implementation). However, we will point out if and when there are different DSL design options depending on which of the two approaches is used.

### 1.1.5 Design Dimensions

There are typically many different languages suitable for expressing a particular program. In DSL design we are looking for the *optimal* language for expressing programs in a particular domain. There are multiple dimensions in which we can optimize language designs. Often it is not possible to maximize along all dimensions; we have to find a trade-off between properties. We have identified the following technical dimensions of DSL design: *expressivity, coverage, semantics and execution, separation of concerns, completeness, structuring programs, language modularity, and concrete syntax*. In the following sections we will examine each of these dimensions in detail.

## 1.2 Expressivity

One of the fundamental advantages of domain-specific languages is increased expressivity over more general programming languages. Increased expressivity typically means that programs are shorter, and that the semantics are more readily accessible to processing tools (we will get back to this). By making assumptions about the domain of application and encapsulating knowledge about the domain in the language and in its execution strategy (and not just in programs), programs expressed using a DSL can be significantly more concise.

**Refrigerators:** Cooling algorithms expressed with the cooling DSL are ca. five times shorter than the C version that is generated from them. ◀

While it is always possible to produce short but incomprehensible

While in the past projectional text editors have gotten a bad reputation, as of 2011, the tools have become good enough, and computers have become fast enough to make this approach feasible, productive and convenient to use.

**TODO:** ref

programs, overall, shorter programs require less effort to read and write than longer programs, and should therefore be more efficient in software engineering. We will thus assume that, all other things being equal, shorter programs are preferable over longer programs.<sup>3</sup>

The Kolomogorov complexity<sup>4</sup> of an object is the smallest program in some description language that produces the object. In our case the objects of interest are programs in  $P$  and we are interested in designing languages that minimize the size of encodings of programs. We use the notation  $|p_L|$  to indicate the size of program  $p$  as encoded in language  $L$ <sup>5</sup>. The essence is the assumption that, within one language, more complex programs will require larger encodings. We also assume that  $p_L$  is the smallest encoding of  $p$  in  $L$ , i.e. does not contain dead or convoluted code. We can then qualify the expressivity of a language relative to another language.

A language  $L_1$  is *more expressive* than a language  $L_2$  ( $L_1 \prec L_2$ ),  
if for each  $p \in P_{L_1} \cap P_{L_2}$ ,  $|p_{L_1}| < |p_{L_2}|$ .

Typically, we need to qualify this statement and restrict it to the domain of interest.

A language  $L_1$  is *more expressive in domain  $D$*  than a language  $L_2$   
( $L_1 \prec_D L_2$ ),  
if for each  $p \in P_D \cap P_{L_1} \cap P_{L_2}$ ,  $|p_{L_1}| < |p_{L_2}|$ .

A weaker but more realistic version of this statement requires that a language is *mostly* more expressive, but may not be in corner cases: DSLs may optimize for the common case and may require code written in a more general language to cover the corner cases<sup>6</sup>.

DSLs ARE MORE EXPRESSIVE than GPLs in the domain they are built for. But there is also a disadvantage: before being able to write these concise programs, users have to learn the language. This task can be separated into learning the domain itself, and learning the syntax of the language. For people who know the domain, learning the syntax can be simplified by using good IDEs with code completion and quick fixes, as well as with good, example-based documentation. In many cases, DSL users already know the domain, or would have to learn the domain even if no DSL were used. Learning the domain is independent of the language itself. It is easy to see, however, that, if a domain is supported by well-defined language, this can be a good reference for the domain itself. Learning a domain can be simplified by working with a good DSL.

**Pension Plans:** The users of the pension DSL are pension experts. Most of them have spent years describing pension plans

<sup>3</sup> The size of a program may not be the only relevant metric to assess the usefulness of a DSL. For example, if the DSL required only a third of the code to write, but it takes four times as long to write the code per line, there is no benefit for writing programs. However, often when reading programs, less code is clearly a benefit. So it depends on the ratio between writing and reading code whether a DSL's conciseness is important.

<sup>4</sup> M. Li and P. Vitanyi. *An Introduction to Kolmogorov Complexity and Its Applications*. Springer Verlag, third edition edition, 2008

<sup>5</sup> We will abstract over the exact way to measure the size of a program, which can be textual lines of code or nodes in a syntax tree, for example.

Note that optimizing a DSL too far towards conciseness may limit the DSL's ability to cover a substantial part of the relevant programs in the domain, making the DSL useless. We discuss coverage in Section 1.3.

<sup>6</sup> We discuss this aspect in the section on completeness (Section 1.6).

using prose text, tables and (informal) formulas. The DSL provides formal languages to express that same knowledge about the domain. ◀

The same is true for the act of *building* the DSL. The domain has to be scoped, fully explored and systematically structured to be able to build a language that covers that domain. This leads to a deep understanding of the domain itself.

**Refrigerators:** Building the cooling DSL has helped the thermodynamicists and software developers to understand the domain, its degrees of freedom and the variability in refrigerator hardware and cooling algorithms. Also, the architecture of the to-be-generated C application that will run on the device became much more well-structured as a consequence of the separation between reusable frameworks, device drivers and generated code. ◀

### 1.2.1 Expressivity and the Domain Hierarchy

In the definition of expressivity above we are comparing arbitrary languages. The central idea behind domain-specific languages is that progressive specialization of the domain enables progressively more expressive languages. Programs for domain  $D_n \subset D_{n-1}$  expressed in a language  $L_{D_{n-1}}$  typically use a set of characteristic idioms and patterns. A language for  $D_n$  can provide linguistic abstractions for those idioms or patterns, which makes their expression much more concise and their analysis and translation less complex.

**Embedded C:** Embedded C extends the C programming language with concepts for embedded software including state machines, tasks, and physical quantities. The state machine construct, for example, has concepts representing states, events, transitions and guards. Much less code is required compared to switch/case statements or cross-pointing integer arrays, two typical idioms for state machine implementation in C. Program analysis, such as finding states that can never be left because no transition leads out of them, is trivial. ◀

**WebDSL:** WebDSL entity declarations abstract over the boilerplate code required by the Hibernate framework for annotating Java classes with object-relational mapping annotations. This reduces code size by an order of magnitude <sup>7</sup>. ◀

<sup>7</sup>E. Visser. WebDSL: A case study in domain-specific language engineering. In *GTTSE*, pages 291–373, 2007

### 1.2.2 Linguistic vs. In-Language Abstraction

*Linguistic Abstraction* By making the concepts of  $D$  first class members of a language  $L_D$ , i.e. by defining linguistic abstractions for these concepts, they can be uniquely identified in a  $D$  program and

their structure and semantics is well defined. No semantically relevant<sup>8</sup> idioms or patterns are required to express interesting programs in  $D$ . Consider the two examples of loops in a Java-like language:

```
int[] arr = ...
for (int i=0; i<arr.size(); i++) {
    sum += arr[i];
}

int[] arr = ...
List<int> l = ...
for (int i=0; i<arr.size(); i++) {
    l.add( arr[i] );
}
```

The left loop can be parallelized, since the order of summing up the array elements is irrelevant. The right one cannot, since (we presume) the order of the elements in the *List* class is relevant. A transformation engine that translates and optimizes the programs must perform (sophisticated, and sometimes impossible) program analysis to determine that the left loop can indeed be parallelized. The following alternative expression of the same behaviour uses better linguistic abstractions, because it is clear without analysis that the first loop can be parallelized and the second cannot. The decision can simply be based on the language concept used (*for* vs. *seqfor*)

```
for (int i in arr) {
    sum += i;
}

seqfor (int i in arr) {
    l.add( arr[i] );
}
```

**Embedded C:** State machines are represented with first class concepts. This enables code generation, as well as meaningful validation. For example, it is easy to detect states that are not reached by any transition and report this as an error. Detecting this same problem in a low-level C implementation requires sophisticated analysis on the switch-case statements or indexed arrays that constitute the implementation of the state machine. ◀

Linguistic abstraction also means that no details irrelevant to the model purpose are expressed. Once again, this increases conciseness, and avoids the undesired specification of unintended semantics (overspecification). Overspecification is bad because it limits the degrees of freedom available to a transformation engine. In the example above, the loop A is over-specified: it expresses ordering of the operations, although this is (most likely) not intended by the person who wrote the code.

**Embedded C:** State machines can be implemented as switch/case blocks or as arrays pointing into each other. The DSL program does not specify which implementation should be used and the transformation engine is free to choose the more appropriate representation, for example, based on desired program size or performance characteristics. Also, log statements and task declarations can be translated in different ways depending on the target platform. ◀

<sup>8</sup> By "semantically relevant" we mean that the tools needed to achieve the model purpose (analysis, translation) have to treat these cases specially.

The property of a language  $L_D$  of having first-class concepts for abstractions relevant in  $D$  is often called *declarativeness*: no sophisticated pattern matching or program flow analysis is necessary to capture the semantics of a program (relative to the purpose), and treat it correspondingly.

**Embedded C:** Another good example is optional ports in components. Components define required ports that specify the interfaces they *use*. For each component instance, a required port is connected to the provided port of an instance of a component that provides a port with a compatible interfaces. Required ports may be optional, so for a given instance, it may be connected or not. Invoking an operation on an unconnected required port would result in an error, so this has to be prevented. This can be done by enclosing the invocation on a required port in an if statement, checking whether the port is connected. However, an if statement can contain any arbitrary boolean expression as its condition (e.g. `if (isConnected(port) || true) { port.doSomething(); }`). So checking *statically* that the invocation only happens if the port is connected is impossible. A better solution based on linguistic abstraction is to introduce a new language concept that checks for a connected port directly: `with port (port) { port.doSomething(); }`. The `with port` statement doesn't use a complete expression as its argument, but only a reference to an optional required port. This way, the IDE can check that an invocation on a required optional port `port` is only done inside of a `with port` statement on that same port. ◀

*In-Language Abstraction* Conciseness can also be achieved by a language providing facilities to define new (non-linguistic) abstractions in programs. It is *not* a sign of a bad DSL if it has in-language abstraction mechanisms as long as the created abstractions don't require special treatment by analysis or processing tools — at which point they should be refactored into linguistic abstractions.

**Refrigerators:** The language does not support the construction of new abstractions since its user community are non-programmers who are not familiar with defining abstractions. As a consequence, the language had to be modified several times during development as new requirements came up from the end users, and had to be integrated directly into the language. ◀

**Embedded C:** Since C is extended, C's abstraction mechanisms (functions, structs, enums) are available. Moreover, we added new mechanisms for building abstractions including interfaces and components. ◀

**WebDSL:** WebDSL provides *template definitions* to capture partial web pages including rendering of data from the database and form request handling. User defined templates can be used to

**TODO:** draw a small component/port diagram to illustrate the idea

GPL concepts for building new abstractions include procedures, classes, or functions and higher-order functions.

build complex user interfaces. ◀

*Standard Library* If a language provides support for in-language abstraction, these facilities can be used by the language *designer* to provide functionality to language users. Instead of adding language features, a standard library is deployed along with the language to all its users. This approach keeps the language itself small, and allows subsequent extensions of the library without changing the language definition and processing tools.

**Refrigerators:** Hardware building blocks have properties. For example, a *fan* can be turned *on* or *off*, and for a *compressor*, the *rpm* can be specified. The set of properties available for the various building blocks is defined via a standard library and is not part of the language. This way, if a new device driver supports a new property, it can be made available to cooling programs without changing and redeploying the language. ◀

This approach is of course well known from programming languages. All of them come with a standard library, and the language can hardly be used without relying on it. It is effectively a part of the language

*Linguistic vs. In-Language Abstraction* A language that contains linguistic abstractions for all relevant domain concepts is simple to transform; the transformation rules can be tied to the identities of the language concepts. It also makes the language suitable for domain experts, because relevant domain concepts have a direct representation in the language. Code completion can provide specific and meaningful support for "exploring" how a program should be written. However, using linguistic abstractions extensively requires that the relevant abstractions be known in advance, or frequent evolution of the language is necessary. In-language abstraction is more flexible, because users can build just those abstractions they need. However, this requires that users are actually trained to build their own abstractions. This is often true for programmers, but it is typically not true for domain experts.

Using a standard library may be a good compromise where one set of users develops the abstractions to be used by another set of developers. This is especially useful if the same language should be used for several, related projects or user groups. Each can build their own set of abstractions in the library. It should be kept in mind that in-language abstraction only works if the transformation of these abstractions is not specific to the abstraction. In such case, linguistic abstraction is better suited.

Modular language extension, as discussed later in Section 1.8.2, provides a middle ground between the two approaches. A language can be flexibly extended, while retaining the advantages of linguistic abstraction.

### 1.2.3 Language Evolution Support

If a language uses a lot of linguistic abstraction, it is likely, especially during the development of the language, that these abstractions

change. Changing language constructs may break existing models, so special care has to be taken regarding language evolution.

Doing this requires any or all of the following: a strict configuration management discipline, versioning information in the models to trigger compatible editors and model processors, keeping track of the language changes as a sequence of change operations that can be "replayed" on existing models, or model migration tools to transform models based on the old language into the new language.

Whether model migration is a challenge or not depends on the tooling. There are tools that make model evolution a very smooth, but many environments don't. Consider this when deciding about the tooling you want to use!

It is always a good idea to minimize those changes to a DSL that break existing models. Backward-compatibility and deprecation are techniques well worth keeping in mind when working with DSLs. For example, instead of just changing an existing concept in an incompatible way, you may add a new concept in addition to the old one, along with deprecation of the old one and a migration script or wizard. Note that you might be able to instrument your model processor to collect statistics on whether deprecated language features continue to be used. Once no more instances show up in models, you can safely remove the deprecated language feature..

If the DSL is used by a closed, known user community that is accessible to the DSL designers, it will be much easier to evolve the language over time because users can be reached, making them migrate to newer versions<sup>9</sup>. Alternatively, the set of all models can be migrated to a newer version using a script provided by the language developers. In case the set of users, and the DSL programs, are not easily accessible, much more effort must be put into keeping backward compatibility, the need for evolution should be reduced<sup>10</sup>.

Using a set of well-isolated viewpoint-specific DSLs prevents rippling effects on the overall model in case something changes in one DSL.

#### 1.2.4 Configuration vs. Customization

Note the difference between configuration and customization. A customization DSL provides a vocabulary which you can creatively combine into sentences of potentially arbitrary complexity. A configuration DSL consists of a well-defined set of parameters for which users can specify values. Configuration languages are more limited, since you cannot easily express instantiation and the relationship between things. However, they are also typically less complex. Hence, the more you can lean towards the configuration side, the easier it usually is to build model processors. It is also simpler from the user's perspective,

In parser-based languages, you can always at the very least open the file in a text editor and run some kind of global search/replace to migrate the program. In projectional editor, special care has to be taken to enable the same functionality.

<sup>9</sup> The instrumentation mentioned above may even report back uses of deprecated language features after the official expiration date.

<sup>10</sup> This is the reason why many GPLs can never get rid of deprecated language features.

Think: feature models. We will elaborate on this in the section of product lines  
**TODO:** ref

since the apparent complexity is limited.

### 1.2.5 Precision vs. Algorithm

Be aware of the difference between precision and algorithmic completeness. Many domain experts are able to formally and precisely specify facts about their domain (the "what" of a domain) while they are not able to define (Turing-complete) algorithms to implement the system (the "how"). It is the job of software developers to provide a formal language for domain users to express facts, and then to implement generators and interpreters to map those facts into executable algorithms that truthfully implement the facts they expressed. The DSL expresses the "what", the model processor adds the "how". Consider creating an incomplete language (Section 1.6), and have developers fill in the algorithmic details in GPL code.

**Pension Plans:** Pension rules are declarative in the sense that a set of mathematical equations and calculation rules are defined. The code generator, written by developers, creates a scalable and sufficiently fast optimization from the models. ◀

## 1.3 Coverage

A language  $L$  always defines a domain  $D$  such that  $P_D = P_L$ . Let's call this domain  $D_L$ , i.e. the domain determined by  $L$ . This does not work the other way around. Given a domain  $D$  there is not necessarily a language that *fully covers* that domain unless we revert to a universal language at a  $D_0$  (cf. the hierarchical structure of domains and languages).

A language  $L$  *fully covers* domain  $D$ , if for each program  $p$  in the domain  $P_D$  a program  $p_L$  can be written in  $L$ . In other words,  $P_D \subseteq P_L$ .

Full coverage is a Boolean predicate; a language fully covers a domain or it does not. In practice, many languages do not fully cover their respective domain. We would like to indicate the *coverage ratio*. The domain coverage ratio of a language  $L$  is the portion of programs in a domain  $D$  that it can express. We define  $C_D(L)$ , the *coverage of domain  $D$  by language  $L$* , as

$$C_D(L) = \frac{\text{number of } P_D \text{ programs expressable by } L}{\text{number of programs in domain } D} = \frac{|P_D - (P_D - P_L)|}{|P_D|}$$

Since  $P_L$  can be larger than  $P_D$ ,  $P_D - (P_D - P_L)$  denotes the  $P_D$  programs that can be expressed in  $P_L$ . Although this equation does not

Note that we can achieve full coverage by making  $L$  too general. Such a language, may, however, be less expressive, resulting in bigger (unnecessarily big) programs. Indeed this is the reason for designing DSLs in the first place: general purpose languages are too general.

make sense from a set theory perspective (all sets are typically infinite), it does describe the intuitive notion of the coverage ratio.

At first glance, an ideal DSL will cover all of its domain ( $C_D(L_D)$  is 100%). It requires, however, that the domain is well-defined and we can actually know what full coverage is. Also, over time, it is likely that the domain evolves and grows, and the language has to be continuously evolved to keep coverage full.

There are two reasons for a DSL *not* to cover all of its *own* domain  $D$ . First, the language may be deficient and needs to be redesigned. This is especially likely for new and immature DSLs. Scoping the domain for which to build a DSL is an important part of DSL design.

Second, the language may have been defined expressly to cover only a subset of  $D$ , typically the subset that is most commonly used. Covering all of  $D$  may lead to a language that is too big or complicated for the intended user community because of its support for rarely used corner cases of the domain. In this case, the remaining parts of  $D$  may have to be expressed with code written in  $D_{-1}$  (see also Section 1.6). This requires coordination between DSL users and  $D_{-1}$  users, if this not the same group of people.

As the domain evolves, language evolution has to keep pace, requiring responsive DSL developers. This is an important process aspect to keep in mind!

**WebDSL:** WebDSL defines web pages through "page definitions" which have formal parameters. Navigate statements generate links to such pages. Because of this stylized idiom, the WebDSL compiler can check that internal links are to existing page definitions, with arguments of the right type. The price that the developer pays is that the language does not support free form URL construction. Thus, the language cannot express all types of URL conventions and does not have full coverage of the domain of web applications. ◀

**Refrigerators:** After trying to write a couple of algorithms, we had to add a *perform ... after  $t$*  statement to run a set of statements after a specified time  $t$  has elapsed. In the initial language, this had to be done manually with events and timers. Since this is a very typical case, we added first-class support. ◀

**Embedded C:** Coverage of this set of languages is full, although any particular extension to C may only cover a part of the respective domain. However, even if no suitable linguistic abstraction is available for some domain concept, it can be implemented in the  $D_0$  language C, while retaining complete syntactic and semantic integration. Also, additional linguistic abstractions can be easily added because of the extensible nature of the overall approach. ◀

## 1.4 Semantics and Execution

Semantics can be partitioned into static semantics and execution semantics. Static semantics represent the constraints and type system rules. Execution semantics denote the observable behaviour of a program  $p$  as it is executed. In this section we focus on execution semantics unless stated otherwise.

Using a function  $OB$  that defines this observable behaviour we can define the semantics of a program  $p_{L_D}$  by mapping it to a program  $q$  in a language for  $D_{-1}$  that has the same observable behavior:

$$\text{semantics}(p_{L_D}) := q_{L_{D-1}} \quad \text{where } OB(p_{L_D}) == OB(q_{L_{D-1}})$$

Equality of the two observable behaviors can be established with a sufficient number of tests, or with model checking and proof in rare cases. This definition of semantics reflects the hierarchy of domains and works both for languages that describe only structure, as well as for those that include behavioural definitions. The technical implementation of the mapping to  $D_{-1}$  can be provided in two different ways: a DSL program can literally be transformed into a program, or a  $L_{D-1}$  interpreter can be written in  $L_{D-1}$  or  $L_{D_0}$  to execute the program.

### 1.4.1 Static Semantics/Validation

Before establishing the execution semantics by transforming or interpreting the program, its static semantics has to be validated. Constraints and type systems are used to this end and we describe their implementation in the DSL Implementation section of this book. Here is a thought overview.

Constraints are simply boolean expressions that establish some property of a model. For example, one might verify that the names of a set of attributes of some entity are unique. For a model to be statically correct, all constraints have to evaluate to true. Constraint checking should only be performed for a model that is structurally/syntactically correct.

Type systems are a special kind of constraints. Consider the example of `var int x = 2 * someFunction(sqrt(2));`. The type system constraint may check that the type of the variable is the same or a supertype of the type of the initialization expression. However, establishing the type of the evaluation expression is non-trivial, since it can be an arbitrarily complex expression. A type system defines the rules to establish the types of arbitrary expressions, as well as type checking constraints.

When designing the constraints and type system in a language, a decision has to be made between (a) declaration of intent and check-

ing for conformance and (b) deriving characteristics and checking for consistency. Consider the following examples.

**Embedded C:** Variables have to be defined in the way shown above, where a type has to be specified. Alternatively, a type system could be built to automatically derive the type of the variable declaration, an approach called type inference. This would make the following code correct: `var x = 2 * someFunction(sqrt(2));`. Since no type is explicitly specified, the validator will infer the type of `x` to be the type calculated for the init expression. ◀

**Embedded C:** State machines that are supposed to be verified by the model checker have to be marked as *verified*. In that case, constraints kick in that mark certain ways of writing actions as invalid, because they cannot be handled by the model checker. An alternative approach could check the model whether these "un-verifiable" ways of writing actions are used, and if so, mark the state machine as not verifiable. ◀

**Pension Plans:** Pension plans can inherit from other plans. If a pension calculation rule overrides a rule in the base plan, then the overriding rule has to be marked as *overrides*. This way, if the rule in the base plan is removed or renamed, the sub plan can report an error. An alternative implementation would simply derive the fact that a rule overrides another one if they have the same name and signature. ◀

Note how in all three cases the constraint checking is based on two steps. First we declare an intent (variable is intended to be int, this state machine is intended to be verifiable, this rule is intended to override another one). We can then check if the program conforms to this specification. The alternative would derive the fact from the program (the variable's type is whatever the expression's type evaluates to, state machines are verifiable if the "forbidden" features aren't used, rules override another one if they have the same name and signature).

When designing constraints and type systems, a decision has to be made regarding when to use which approach. Here are some trade-offs. The specification/conformance approach requires a bit more code to write, but results in more meaningful and specific error messages. The message can express that fact that one part of a program does not conform to a specification made by another part of the program. It also anchors the constraint checker, because a fixed fact about the program is explicitly given, instead of having it derived from a (possibly large) part of the the program. The derivation/consistency approach is less effort to write and can hence be seen to be more convenient, but it requires more effort in constraint checking, and error messages may be

harder to understand because of the missing, explicit "hard fact" about the program.

#### 1.4.2 Transformation

The transformation case is easy to see: a transformation recreates those patterns and idioms in  $L_{D-1}$  for which  $L_D$  provides linguistic abstraction. The result may be transformed further, until a level is reached for which a language with an execution infrastructure exists — often  $D_0$ . Code generation from a DSL is thus a special case where  $L_{D_0}$  code is generated.

**Embedded C:** The semantics of state machines are defined by their mapping back to C switch-case statements. This is repeated for higher D languages. The semantics of the robot control DSL is defined by its mapping to state machines and tasks. To explain the semantics to the users, prose documentation is available as well. ◀

**Component Architecture:** The component architecture DSL only described interfaces, components and systems. This is all structure-only. Many constraints about structural integrity are provided, and a mapping to OSGi is implemented. The formal definition of the semantics are implied by the mapping to OSGi ◀

Formally, defining semantics happens by mapping the DSL concepts to  $D_{-1}$  concepts for which the semantics is known. For DSLs used by developers, and for domains that are defined bottom-up, this works well. For domain expert DSLs, and for domains define top-down this approach is not necessarily good enough, since the  $D_{-1}$  concepts has no inherent meaning to the users and/or the domain. An additional way of defining the meaning of the DSL is required. Useful approaches include prose documentation as well as test cases or simulators. These can be written in (another part of the) DSL itself; this way, domain users can play with the DSL and write down their expectations in the testing aspect.

**Refrigerators:** This DSL has a separate viewpoint for defining test cases where domain experts can codify their expectations regarding the behaviour of cooling programs. An interpreter is available to simulate the programs, observe their progress and stimulate them to see how they react. ◀

**Pension Plans:** This DSL supports an Excel-like tabular notation for expressing test cases for pension calculation rules. The calculations are functional, and the calculation tree can be extended as a way of debugging the rules. ◀

*Multi-staged Transformation* For languages where the semantic gap between the DSL and the target language is significant, it makes sense to introduce intermediate languages so the transformation can be modularized. Optimizations can be performed on each level, exploiting the properties of that particular abstraction level. Modern compilers with multiple intermediate representations are a good example for this approach. Reusing lower  $D$  languages and their subsequent transformations includes reuse of non-trivial analyses or optimizations. This makes this case much more useful than what the pure reuse of languages and transformations suggests. Splitting a transformation into a chain of smaller ones also makes each of them easier to understand and maintain.

**Embedded C:** The extensions to C are all transformed back to C idioms during transformation. Higher-level DSLs, for example, a simple DSL for robot control, are reduced to C plus some extensions such as state machines and tasks. ◀

We can learn something else from compilers: they can be retargeted relatively easily by exchanging the backends (machine code generation phases) or the frontend (programming language parsers and analyzers). For example, GCC can generate code for many different processor architectures (exchangeable backends), and it can generate backend code for several programming languages, among them C, C++ and Ada (exchangeable frontends). The same is possible for DSLs. The same high  $D$  models can be executed differently by exchanging the lower  $D$  intermediate languages and transformations. Or the same lower  $D$  languages and transformations can be used for different higher  $D$  languages, by mapping these different languages to the same intermediate language.

**Embedded C:** The embedded C language (and some of its higher  $D$  extensions) have various translation options, for several different target platforms (Win32 and Osek), an example of backend reuse. ◀

A special case of a multi-staged transformation is as a preprocessor to a code generator. Here, a transformation is used to reduce the set of used language concepts in a fragment to a minimal core, and only the minimal core is supported in the code generator.

**Embedded C:** Consider the case of a state machine where you want to be able to add an "emergency stop" feature, i.e. a new transition from each existing state to a new STOP state. Don't handle this in the generator templates. Rather, write a model transformation script that preprocesses the state machine model and adds all the new transitions and the new STOP state. Once done,

MPS comes with a transformation engine that makes such transformation chains easy to implement.

This is the reason why we usually generate GPL source code from DSLs, and not machine code: we want to reuse existing transformations and optimizations provided by the GPL compiler and/or runtime.

you can run the existing generator unchanged. You have effectively modularized the emergency stop concern into the transformation. ◀

**Component Architecture:** The DSL describes hierarchical component architectures (where components are assembled from interconnected instances of other components). Most component runtime platforms don't support such hierarchical components, so you need to "flatten" the structure for execution. Instead of trying to do this in the code generator, you should consider an M2M step to do it, and then write a simpler generator that works with a flattened, non-hierarchical model. ◀

*Care about generated code* Ideally, generated code is a throw-away artifact, a bit like object files in a C compiler. However, that's not quite true. When integrating with generated code, you will have to read the generated code, understand it (to some extent), and you will also have to debug it at some point. Hence, generated code should be documented, use good names for identifiers, and be indented correctly. All of this is relatively easy to achieve, as you have all the information you need when writing the code generator! Making generated code adhere to the same standards as manually written code also helps to diffuse some of the skepticism against code generation that is still widespread in some organizations.

*Platform* Code generators can become complex. The complexity can be reduced by splitting the overall transformation into several steps — see above. Another approach is to work with a manually implemented, rich domain specific platform. It typically consists of middleware, frameworks, drivers, libraries and utilities that are taken advantage of by the generated code.

Where the generated code and the platform meet depends on the complexity of the generator, requirements regarding code size and performance, the expressiveness of the target language and the potential availability of libraries and frameworks that can be used for the task.

In the extreme case, the generator just generates code to populate/configure the frameworks (which might already exist, or which you have to grow together with the generator) or provides statically typed facades around otherwise dynamic data structures. Don't go too far towards this end, however: in cases where you need to consider resource or timing constraints, or when the target platform is predetermined and perhaps limited, code generation does open up a new set of options and it is often a very good approach (after all, it's basically the same as compilation, and that's a proven and important

Note that in complete languages with full coverage (i.e. where 100% of the  $D_{-1}$  code is generated), the generated code is never seen by a DSL user. In this case the statements made here don't apply.

Figure 1.4: Typical layering structure of an application created using DSLs.

Figure 1.5: Stalagmites and stalactites in limestone caves as a metaphor for a generator and a platform.

technique).

**Embedded C:** For most aspects, we use only a very shallow platform. This is mostly for performance reasons and for the fact that the subset of C that is often used for embedded systems does not provide good means of abstraction. For example, state machines are translated to switch/case statements. If we would generate Java code in an enterprise system, we may populate a state machine framework instead. In contrast, when we translate the component definitions to the AUTOSAR target environment, a relatively powerful platform is used — namely the AUTOSAR APIs, conventions and generators. ◀

### 1.4.3 Interpretation

For interpretation, the same approach could be used, i.e. an interpreter for  $L_D$  can be implemented in  $L_{D-1}$ . However, in practice we see interpreters written in  $L_{D_0}$ . They may be extensible, so new interpreter code can be added in case specialized languages define new language concepts. We have not come across real-world DSLs where interpreters are stacked along the domain hierarchy in the same way as transformations, with interpreters for  $L_{D_n}$  written in  $L_{D_{n-1}}$  for  $n > 1$ .

**Refrigerators:** The DSL also supports the definition of unit tests for the asynchronous, reactive cooling algorithm. These tests are executed with an in-IDE interpreter. A simulation environment allows the interpreter to be used interactively. Users can "play" with a cooling program, stepping through it in single steps, watching values change. ◀

**Pension Plans:** The pension DSL supports the in-IDE execution of rule unit tests by an interpreter. In addition, the rules can be debugged. The rule language is functional, so the debugger "expands" the calculation tree, and users can inspect all intermediate results. ◀

### 1.4.4 Transformation vs. Interpretation

A primary concern in semantics is the decision between transformation (code generation) and interpretation. Here are a couple of criteria to help with this decision.

*Code Inspection* When using code generation, the resulting code can be inspected to check whether it resembles code that had previously been written manually in the DSL's domain. Writing the transformation rules can be guided by the established patterns and idioms in D-1. Interpreters are meta programs and as such harder to relate to the existing code patterns.

*Debugging* Debugging generated code is straight forward if the code is well structured (which is up to the transformation). Debugging interpreters is harder, because setting breakpoints in the DSL program requires the use of conditional breakpoints, which are typically cumbersome to use.

*Performance and Optimization* The code generator can include optimizations that result in small and tight generated code. The compiler for the generated code may come with its own optimizations which are used automatically if source code is generated. Generally, performance is better in generated environments, since interpreters always imply an additional layer of indirection.

*Platform Conformance* Generated code can be tailored to any target platform. The code can look exactly as manually written code, no support libraries are required. This is important for systems where the source code (and not the DSL code) is the basis for a contractual obligation or for review and/or certification. Also if artifacts need to be generated for the platform that are not directly executable (descriptors, meta data), code generation is more suitable.

*Turnaround Time* Turnaround time for interpretation is better than for generation: no generation, compilation and packaging step is required. Especially for target languages with slow compilers, large amounts of generated code can be a problem.

*Runtime Change* In interpreted environments, the DSL program can be changed as the target system runs; the editor can be integrated into the executing system. The term data-driven system is often used in this case.

#### 1.4.5 Sufficiency

A fragment is *sufficient for transformation T* if the fragment itself contains all the data for the transformation to be executed. It is *insufficient* if it is not. While dependent fragments are by definition not sufficient without the transitive closure of fragments they depend on, an independent fragment may be sufficient for one transformation, and insufficient for another.

**Refrigerators:** The hardware structure is sufficient for a transformation that generates an HTML doc that describes the hardware. It is insufficient regarding the C code generator, since the behavior fragment is required as well. ◀

**Embedded C:** The MED code is sufficient regarding the MED-to-C generator. It is not sufficient regarding the MED-to-Osek

generator, since a so-called *system specification* fragment is required to define how the mapping to Osek should look like. ◀

#### 1.4.6 Synchronizing Multiple Mappings

The approach suggested so far works well if we have only one mapping of a DSL for execution. The semantics implied by the mapping to  $L_{D-1}$  can be *defined* to be correct. However, as soon as we transform the program to several different targets in  $D_{-1}$  using several transformations, we have to ensure that the semantics of all resulting programs are identical. In practice, this often happens when an interpreter is used in the IDE for "experimenting" with the models, and a code generator creates efficient code for execution in the target environment. In this case, we recommend providing a set of test cases that are executed both the interpreted and generated versions, expecting them to succeed in both. If the coverage of these test cases is high enough to cover all of the observable behavior, then it can be assumed with reasonable certainty that the semantics are the same.

**Pension Plans:** The unit tests in the pension plans DSL are executed by an interpreter in the IDE. However, as Java code is generated from the pension plan specifications, the same unit tests are also executed by the generated Java code, expecting the same results as in the interpreted version. ◀

#### 1.4.7 Choosing between Several Mappings

Sometimes there are several *alternative* ways how a program in  $L_D$  can be translated to a single  $L_{D-1}$ , for example to realize different non-functional requirements (optimizations, target platform, tracing or logging). There are several ways how one alternative may be selected.

- Heuristics, based on patterns and idioms used in the program, can be used to determine the applicable translation from the program. Codifying these rules and heuristics can be hard.
- In analogy to compiler switches, the decision can be controlled by additional, external data, for example by adding an annotation model. An annotation model contains data used by the transformation to decide how to translate the core program. The transformation uses the  $L_D$  program and the annotation model as its input. There can be several different annotation models for the same core model.
- Alternatively,  $L_D$  can be extended to contain additional data to guide decision. This is only useful if the DSL user can actually de-

cide which alternative to choose, and if only one alternative should be chose for each program.

As we have suggested above in the case of multiple transformations of the same  $L_D$  program, here too extensive testing must be used to make sure that all translations exhibit the same semantics (except for the non-functional characteristics that are expected to be different).

#### 1.4.8 *Reduced Expressiveness*

It may be beneficial to limit the expressiveness of a language. Limited expressiveness often results in more sophisticated analyzability. For example, while state machines are not very expressive, sophisticated model checking algorithms are available (e.g. using the SPIN model checker from <http://spinroot.com/>). The same is true for first-order logic, where satisfiability (SAT) solvers<sup>11</sup> can be used to check programs for consistency. If these kinds of analysis are useful for the model purpose, then limiting the expressiveness to the respective formalism may be a good idea, even if it makes expressing certain programs in  $D$  more cumbersome.

However, the language may have to be reduced to the point where domain experts are not able to use the language because the connection to the domain is too loose. An alternative approach is to use a language with limited expressiveness at  $D_{-1}$ . For analysis and verification, the  $L_D$  concepts are translated down into the verifiable  $L_{D-1}$  language. Verification is performed on  $L_{D-1}$ , mapping the results back to  $L_D$ . Transforming to a verifiable formalism also works if the formalism is not at  $D_{-1}$ , as long as a mapping exists. The problem with this approach is the interpretation of analysis results in the context of the DSL. Domain users may not be able to interpret the results of model checkers or solvers, so they have to be translated back to the DSL. This may be a lot of work, or even impossible.

**Embedded C:** The state machines expressed in the statemachine extension can be verified with a model checker. To make this possible, state machine cannot use arbitrary C code in its actions. Instead, an action can only change the values of variables local to the state machine and set output events. These output events can then be mapped to C functions or component runnables whose implementation is outside the scope of the verification. The key here is that the state machine is completely self-contained regarding verification: adapting the state machine to its surrounding C program is a separate concern and irrelevant to the model checker. ◀

**Refrigerators:** For the cooling algorithm, we are working on a mapping to SPIN/Promela formalism to perform model checking

<sup>11</sup> D. G. Mitchell. A sat solver primer. *eatcs*, 85:112–132, 2005

on the pumping algorithms. This will be used to proof that invariants expressed in the pumping program will hold in all cases, or to show counter examples if they do not. ◀

## 1.5 Separation of Concerns

A domain  $D$  can be composed from different concerns. Fig. 1.6 shows  $D_{1.1}$  composed from the concerns A, B and C. To describe a complete program for  $D$ , the program needs to address all the concerns.

Two fundamentally different approaches are possible to deal with the set of concerns in a domain. Either a single, integrated language can be designed that addresses all concerns of  $D$  in one integrated model. Alternatively, separate concern-specific DSLs can be defined, each addressing one or more of the domain's concerns. A program then consists of a set of dependent, concern-specific fragments that relate to each other in a well-defined way. Viewpoints support this separation of domain concerns into separate DSL. Fig. 1.7 illustrates the two different approaches.

**Embedded C:** The tasks language module includes the task implementation as well as task scheduling in one language construct. Scheduling and implementation are two concerns that could have been separated. We opted against this, because both concerns are specified by the same person. The language used for implementation code is `med.core`, whereas the task constructs are defined in the `med.tasks` module. So the languages are modularized, but they are used in a single integrated model. ◀

**WebDSL:** Web programs consists of multiple concerns including persistent data, user interface, and access control. WebDSL provides specific languages for these concerns, but *linguistically integrates* them into a single language<sup>12</sup>. Declarations in the languages can be combined in WebDSL modules. A WebDSL developer can choose how to factor declarations into modules; e.g. all access control rules in one module, or all aspects of some feature together in one module. ◀

For embedded software, these could be component and interface definitions (A), component instantiation and connections (B), as well as scheduling and bus allocation (C).

Figure 1.6: A domain may consist of several concerns. A domain is covered either by a DSL that addresses all of these concerns, or by a set of related, concern-specific DSLs.

<sup>12</sup> Z. Hemel, D. M. Groenewegen, L. C. L. Kats, and E. Visser. Static consistency checking of web applications with WebDSL. *JSC*, 46(2):150–182, 2011

Figure 1.7: Part A shows an integrated DSL, where the various concerns (represented by different line styles) are covered by a single integrated language (and consequently, one model). Part B shows several viewpoint languages (and model fragments), each covering a single concern. Arrows in Part B highlight dependencies between the viewpoints.

If viewpoints are used, the concern-specific languages, and consequently the viewpoint models, should have well-defined dependencies; cycles should be avoided. If dependencies between viewpoint fragments are kept cycle-free, the independent fragments may be sufficient for certain transformations; this can be a driver for using viewpoints in the first place.

### 1.5.1 Viewpoints to modularize Programs

Separating out a domain concern into a separate viewpoint fragment can be useful for several reasons.

If different concerns of a domain are specified by different stakeholders then separate viewpoints make sure that each stakeholder has to deal only with the information they care about. The viewpoint separation has to be aligned with the development process: the order of creation of the fragments must be aligned with the dependency structure.

Viewpoints are also a good fit if the independent fragment is also sufficient for a transformation in the domain, i.e. it can be processed without the presence of the additional concerns expressed in separate viewpoints.

Another reason for separate viewpoints is a 1:n relationship between the independent and the dependent fragments. If a single core concern may be enhanced by several different additional concerns, then it is crucial to keep the core concern independent of the information in the additional concerns. Viewpoints enable this.

**Refrigerators:** One concern in this DSL specifies the logical hardware structure of refrigerators installations. The other one describes the refrigerator cooling algorithm. Both are implemented as separate viewpoints, where the algorithm DSL references the hardware structure DSL. Using this dependency structure, different algorithms can be defined for the same structure. Each of these algorithms resides in its own model. While the C code generation requires both behavior and hardware structure fragments, the hardware fragment is sufficient for a transformation that creates a visual representation of the hardware structures. ◀

The IDE should provide navigational support: If an element in viewpoint B points to an element in viewpoint A then it should be possible to follow this reference ("Ctrl-Click"). It should also be possible to query the dependencies in the opposite direction ("find the persistence mapping for this entity" or "find all UI forms that access this entity").

A final (very pragmatic) reason for using viewpoints is when the tooling used does not support embedding of a reusable language because syntactic composition is not supported.

### 1.5.2 Viewpoints as Annotation Models

A special case of viewpoint separation is annotation models. When working with model-to-model transformations you can run into some of the same problems as with code generation in that sometimes, it seems necessary to mark up the result of a transformation step manually before it is further processed. Actually changing the model after it has been created via a transformation would be an approach similar to protected regions with similar challenges.

The better solution is to create a separate model — an annotation model — that references the elements in the intermediate model for which it specifies additional model data. The downstream processor would process the model created via the upstream model-to-model transformation and the annotation model in conjunction, understanding the semantics of the annotation model's relationship to the original model.

**Example:** For example, if you create a relational data model from an object oriented data model, you might automatically derive database table names from the name of the class in the OO model. If you need to "change" some of those names, use an annotation model that specifies an alternate name. The downstream processor knows that the name in the annotation model overrides the name in the original model. ◀

### 1.5.3 Viewpoints for Progressive Refinement

There is an additional use case for viewpoint models not related to the concerns of a domain, but to progressive refinement. Consider complex systems. Development starts with requirements, proceeds to high-level component design and specification of non-functional properties, and finishes with the implementation of the components. Each of these refinement steps may be expressed with a suitable DSL, realizing the various "refinement viewpoints" of the system (Fig. 1.8). The references between model elements are called traces<sup>13</sup>. Since the same conceptual elements may be represented on different refinement levels (e.g. component design and component implementation), synchronization between the viewpoint models is often required (enabled via techniques described in <sup>14</sup>).

### 1.5.4 Viewpoint Synchronization

In some cases the models for the various concerns need to be synchronized. This means that when a change happens in a model of one viewpoint, the models representing other viewpoints must change in a consistent way. It depends on the tools used whether synchronization is feasible: in projectional tools it is relatively easy to achieve, for

<sup>13</sup> W. Jirapanthong and A. Zisman. Supporting product line development through traceability. In *apsec*, pages 506–514, 2005

Figure 1.8: Progressive refinement: the boxes represent models expressed with corresponding languages. The dotted arrows express dependencies, whereas the solid arrows represent references between model elements.

parser-based systems it can be problematic.

**Embedded C:** Components implement interfaces. Each component provides an implementation for each method define in each of the interfaces it implements. If a new method is added to an interface, all components that implement that particular interface must get a new, empty method implementation. This is an example of model synchronization. ◀

#### 1.5.5 Views on Programs

In projectional editors it is also possible to store the data for all viewpoints in the same model tree, while showing different "views" onto the model to materialize the various viewpoints. The particular benefit of this approach is that additional concern-specific views can be defined later, after programs have been created.

**Pension Plans:** Pension plans can be shown in a graphical notation highlighting the dependency structure. The dependencies can still be edited in this view, but the actual content of the pension plans is not shown. ◀

**Embedded C:** Annotations are used for storing requirements traces and documentation information in the models. The program can be shown and edited with and without requirements traces and documentation text. ◀

MPS also provides so-called annotations, where additional model data can be "attached" to any model element, and shown optionally.

## 1.6 Completeness

Completeness refers to the degree to which a language  $L$  implements complete programs. Let us introduce a function  $G$  ("code generator") that transforms a program  $p$  in  $L_D$  to a program  $q$  in  $L_{D-1}$ . For a complete language,  $p$  and  $q$  have the same semantics, i.e.  $OB(p) == OB(G(p)) == OB(q)$ . For incomplete languages where  $OB(G(p)) \subset$

$OB(p)$  we have to write additional code in  $L_{D-1}$ , to obtain a program in  $D_{-1}$  that has the same semantics as intended by the original program in  $L_D$ . In cases where we use several viewpoints to represent various concerns of  $D$ , the set of fragments written for these concerns must be enough for complete  $D_{-1}$  generation. General purpose languages at  $D_0$  are by definition complete.

**Embedded C:** The Embedded C language is complete regarding  $D_{-1}$ , or even  $D-n$  for higher levels of  $D$ , since higher levels are always built as extensions of  $D_{-1}$ . Developers can always fall back to  $D_{-1}$  to express what is not expressible in  $D$ . ◀

**Refrigerators:** This DSL uses several viewpoints: one to define the structure of a refrigerator, and one to describe the actual algorithm. When generating the C code for the algorithm, both viewpoints are needed, because the structure defines how some of the algorithms are implemented. ◀

### 1.6.1 *Compensating for Incompleteness*

Integrating the  $L_{D-1}$  in case of an incomplete  $L_D$  language can be done in several ways:

- by calling "black box" code written in  $L_{D-1}$  (requires concepts for calling  $D_{-1}$  foreign functions in the  $D$  language)
- by directly embedding  $L_{D-1}$  code in the  $L_D$  program (useful if  $L_D$  is an extension of  $L_{D-1}$ , or if the tool provide adequate support for embedding the  $D_{-1}$  language into  $D$  programs.)
- by inserting manually-written  $L_{D-1}$  code into the  $L_{D-1}$  code generated from the  $L_D$  program (using protected regions)
- or by using composition mechanisms of  $L_{D-1}$  (e.g. inheritance) to "plug in" the manually written code into the generated code without actually modifying the generated files (also known as the Generation Gap pattern<sup>15</sup>). Example techniques for realizing this approach include generating a base class with abstract methods (requiring the user to implement them in a manually written subclass) or with empty callback methods which the user can use to customize in a subclass (for example, in user interfaces, you can return a position object for a widget, the default method returns null, default to the generic layout algorithm). You can delegate, implement interfaces, use #include, use reflection tricks, AOP or take a look at the well-known design patterns for inspiration. Some languages provide partial classes, where a class definition can be split over a generated file and a manually written file.

Another way of stating this is that  $G$  produces a program in  $L_{D-1}$  that is not sufficient for a subsequent transformation (e.g. a compiler), only the manually written  $L_{D-1}$  code leads the sufficiency.

Just "pasting text into a textfield" is not a productive approach, since no real integration between the languages is supported. Many tools for graphical modeling provide small boxes in dialogs to enter "target code" without any support. In my opinion, this is not useful!

We strongly discourage the use of protected regions. You'll run into all kinds of problems: generated code is not a throw-away product anymore, you have to check it in, and you'll run into all kinds of funny situations with your CM system. Also, often you will accumulate a "sediment" of code that has been generated from model elements that are no longer in the model (if you don't use protected regions, you can delete the whole generated source directory from time to time, cleaning up the sediment).

<sup>15</sup> J. Vlissidis. Generation gap. C++ Report, 1996

For DSLs used by developers, incomplete DSLs are usually not a problem because they are comfortable with providing the  $D_{-1}$  code expressed in a programming language. Specifically, the DSL users are the same people as those who provide the remaining  $D_{-1}$  code, so coordination between the two not a problem. For DSLs used by domain experts, the situation is different. Usually, they are not able to write  $D_{-1}$  code, so other people (developers) have to fill in the remaining concerns. Alternatively, developers can develop a predefined set of foreign functions that can be called from within the DSL. In effect, developers provide a library of "behavioural building blocks" which can be invoked as black boxes from DSL programs.

This requires elaborate collaboration schemes, because the domain experts have to communicate the remaining concerns via prose text or verbal communication.

**Component Architecture:** This DSL is not complete. Only class skeleton and infrastructure integration code is generated from the models. The component implementation has to be implemented manually in Java using the Generation Gap pattern. ◀

Note that a DSL that does not *cover* all of  $D$  can still be *complete*: the  $L_{D-1}$  code generated from a  $D$  program may require a framework written in  $L_{D-1}$  to run in. That framework represents aspects of  $D$  outside the scope of  $L_D$ .

**Refrigerators:** The cooling DSL only supports reactive, state based systems that make up the core of the cooling algorithm. The drivers used in the lower layers of the system, or the control algorithms controlling the actual compressors, cannot be expressed with the DSL. However, these aspects are developed once and can be reused without adaptations, so using DSLs is not sensible. These parts are implemented manually in C. ◀

**Embedded C:** Control loops and device drivers are outside the scope of the DSL, but are used by the generated code. These parts are manually written and made available to the generated code by well-defined APIs. ◀

**WebDSL:** The core of a web application is concerned with persistent data and their presentation. However, web applications need to perform additional duties outside that core, for which often useful libraries exist. WebDSL provides a *native interface* that allows a developer to call into a Java, library by declaring types and functions from the library in a WebDSL program. ◀

Allowing users to write  $D_{-1}$  code, and especially, if it is actually a GPL in  $D_0$ , comes with two additional challenges though.

*Controlling  $D_{-1}$  code* The following can easily happen: the generator generates an abstract class from some model element. The developer is expected to subclass the generated class and implement a couple of

abstract methods. The manually written subclass needs to conform to a specific naming convention so some other generated code can find and use the manually written subclass. The generator, however, just generates the base class and stops. How do you remind developers to create a subclass?

Of course, if the constructor of the concrete subclass is called from another location of the generated code, and/or if the abstract methods are invoked, you'll get compiler errors. By their nature, they are on the abstraction level of the implementation code, however. It is not always obvious what the developer has to do in terms of the model or domain.

To solve this issue, make sure there is there a way to make those conventions and idioms interactive. One way to do this is to generate checks/constraints *against the code base* and have them evaluated by the IDE, for example using Findbugs etc. If one fails, an error message is reported to the developer. As soon as the developer implements the manual code in the required way, the error message goes away.

*Broken Promises* In many cases, you will implement constraints that validate the DSL program in order to ensure some property of the resulting system. For example, you might check dependencies between components in an architecture model to ensure components can be exchanged in the actual system.

Of course this only works if the manually written code does not introduce dependencies that are not present in the model. In that case the "green light" from the constraint check does not help much.

To ensure that promises made by the models are kept by the code, use the following two approaches. First, generate code that does not allow violation of model promises. For example, don't expose a factory that allows components to look up and use any other component (creating dependencies), but rather use dependency injection to supply objects for the valid dependencies expressed in the model. Second, use architecture analysis tools (dependency checkers) to validate manually written code. You can easily generate the check rules for those architecture analysis tools from the models.

**Component Architecture:** The code generator to Java generates component implementation classes that use dependency injection to supply the targets for required ports. This way, the implementation class will have access to exactly those interfaces specified in the model. An alternative approach would be to simply hand some kind of factory or registry where a component implementation can look up instances of components that provide the interfaces specified by the required ports of the current component.

However, this way it would be much harder to make sure that only those dependencies are accessed that are expressed in the model. Using dependency injection *enforces* this constraint in the implementation code. ◀

### 1.6.2 Roundtrip Transformation

Roundtrip transformation means that an  $L_D$  program can be recovered from a program in  $L_{D-1}$  (written from scratch, or changed manually after generation from a previous iteration of the  $L_D$  program). This is challenging, because it requires reconstituting the semantics of the  $L_D$  program from idioms or patterns used in the  $L_{D-1}$  code. This is the general reverse engineering problem and is not generally possible, although progress has been made over recent years (see for example <sup>16</sup>). For complete languages roundtripping is generally not useful, because the complete program can be written on  $L_D$  in the first place. Even if recovery of the semantics is possible it may not be practical: if the DSL provides significant abstraction over the  $L_{D-1}$  program, then the generated  $L_{D-1}$  program is so complicated, that manually changing the  $D_{-1}$  code in a consistent and correct way is tedious and error-prone.

Roundtripping has traditionally been used with respect to UML models and generated class skeletons. In that case, the abstractions were similar (classes), if the tool basically just provides a different concrete syntax.

**Embedded C:** This language does not support roundtripping, but since all DSLs are extensions of C, one can always add C code to the programs, alleviating the need for roundtripping in the first place. ◀

**Refrigerators:** Roundtripping is not required here, since the DSL is complete. The code generators are quite sophisticated, and nobody would want to manually change the generated C code. Since the DSL has proven to provide good coverage, the need to "tweak" the generated code has not come up. ◀

**Component Architecture:** Roundtripping is not supported. Changes to the interfaces, operation signatures or components have to be performed in the models. This has not been reported as a problem by the users, since both the implementation code and the DSL "look and feel" the same way — they are both Eclipse-based textual editors — and generation of the derived low level code happens automatically on saving a changed model. The workflow is seamless. ◀

<sup>16</sup> D. Beyer, T. A. Henzinger, and G. ThĀ'oduloz. Program analysis with dynamic precision adjustment. In *ASE*, pages 29–38, 2008; M. Pistoia, S. Chandra, S. J. Fink, and E. Yahav. A survey of static analysis methods for identifying security vulnerabilities in software systems. *IBMSJ*, 46(2):265–288, 2007; and M. Antkiewicz, T. T. Bartolomei, and K. Czarnecki. Fast extraction of high-quality framework-specific models from application code. *ASE*, 16(1):101–144, 2009

Notice that the problem of "understanding" the semantics of a program written at a too-low abstraction level is the reason for DSLs in the first place: by providing linguistic abstractions for the relevant semantics, no "recovery" is necessary.

We generally recommend to avoid (the attempt of building support for) roundtripping.

## 1.7 Fundamental Paradigms

Every DSL is different. It is driven by the domain to which it applies. However, as it turns out, there are also a number of commonalities between DSLs. These can be handled by modularizing and reusing (parts of) DSLs as discussed in the *next* section. In *this* section we look at common paradigms for describing DSL structure and behaviour.

**TODO:** cite: Clean up References to this stuff

### 1.7.1 Structure

Languages have to provide means to structure large programs in order to keep them manageable. These include modularization and visibility, specification vs. implementation, specialization, types and instances as well as partitioning.

*Modularization and Visibility* DSL often provide some kind of logical unit structure, such as namespaces or modules. Visibility of symbols may be restricted to those in the same unit, or in referenced ("imported") units. Symbols may be declared as public or private. Most contemporary programming languages use some form of namespaces and visibility restriction as their top level structure.

The language design alternatives described in this section are usually not driven directly by the domain, or the domain experts guiding the design of the language. Rather, they are often brought in by the language designer or the consumers of the DSL as a means of managing overall complexity. For this reason they may be hard to "sell" to domain experts.

Some form of namespaces and visibility is necessary in almost any DSL. Often there are domain concepts that can play the role of the module, possibly oriented towards the structure of the organization in which the DSL is used. Keeping some elements private makes those changeable without consequences for using modules.

**Embedded C:** As a fundamental extension to C, this DSL contains modules with visibility specifications and imports. Functions, state machines, tasks and all other top-level concepts reside in modules. ◀

**Component Architecture:** Components and interfaces live in namespaces. Components are implementation units, and are always private. Interfaces and data types may be public or private. Namespaces can import each other, making the public elements of the imported namespace visible to the importing namespace. The OSGi generator creates two different bundles: an interface bundle that contains the public artifacts, and an implementation bundle with the components. In case of a distributed system, only the interface bundle is deployed on the client. ◀

*Partitioning* Partitioning refers to the breaking down of programs into several physical units such as files. These physical units do not have to correspond to the logical modularization of the models within the

If a repository-based tool is used, the importance of partitioning is greatly reduced. Although even in that case, there may be a set of federated and distributed repositories that can be considered partitions

partitions. Typically each model fragment is stored in its own partition. For example, in Java a public class has to live in a file of the same name (logical module == physical partition), whereas in C# there is no relationship between namespace, class names and the physical file and directory structure. A similar relationship exists between partitions and viewpoints, although in most cases, different viewpoints are stored in different partitions.

Partitioning may have consequences for language design. Consider a DSL where an concept A contains a list of instances of concept B. The B instances then have to be physically nested within an instance of A in the concrete syntax. If there are many instances of B in a given model, they cannot be split into several files. If such a split should be possible, this has to be designed into the language. Other concerns influence the design of a partitioning strategy:

*Change Impact* which partition changes as a consequence of specific changes of the model (changing an element name might require changes to all by-name references to that element in other partitions)

*Link Storage* where are links stored (are they always stored in the model that logically "points to" another one)?, and if not, how/where/when to control reference/link storage.

*Model Organization* Partitions may be used as a way of organizing the overall model. This is particularly important if the tool does not provide a good means of showing the logical structure models and finding elements by name and type. Organizing files, with useful names, in directory structures is a good alternative.

*Tool Chain Integration* integration with existing, file based tool chains. Files may be the unit of checkin/checkout, versioning, branching or permission checking.

**Component Architecture:** A variant of this DSL that was used in another project had to be changed to allow namespaces to be spread over several files for reasons of scalability and version-control granularity. In the initial version, namespaces actually contained the components and interfaces. In the revised version, components and interfaces resided were owned by no other element, but model files (partitions) had a namespace declaration at the top, logically putting all the contained interfaces and components into this namespace. Since there was no technical containment relationship between namespaces and its elements, several files could now declare the same namespace. ◀

Another driver for using partitions is the scalability of the DSL tool. Beyond a certain file size, the editor may become sluggish.

It often makes sense to ensure that each partition is processable separately to reduce processing times. Alternatively, it is possible to explicitly specify the set of partitions that should be processed in a given processor run (or at least a search path, a set of directories, to find the partitions, like an include path in C compilers). You might even consider a separate build step to combine the results created from the separate processing steps of the various partitions (like a C compiler: it compiles every file separately into an object file, and then the linker handles overall symbol/reference resolution and binding).

The partitioning scheme may also influence users' collaboration when editing models. There are two major collaboration models: real-time and commit-based. In real-time collaboration, a user sees his model change when another user changes the same model. Change propagation is immediate. A database-backed repository is often a good choice regarding storage, since the granularity tracked by the repository is the model element. In this case, the partitioning may not be visible to the end user, since they just work "on the repository". This approach is often (at least initially) preferred by non-programmer DSL users.

The other collaboration mode is commit-based where a user's changes only make it to the repository if he performs a *commit*, and incoming changes are only visible after a user has performed an *update*. While this approach can be used with database-backed repositories, it is most often used with file-based storage. In this case, the partitioning scheme is visible to DSL users, because it is those partitions (i.e. files) they commit or update. This approach tends to be preferred by developers, maybe because well-known versioning tools have used the approach for a long time.

*Specification vs. Implementation* Separating specification and implementation supports plugging in different implementations for the same specification and hence provides a way to separate the outside from the inside of something. This supports the exchange of several implementations behind a single interface. This is often required as a consequence of the development process: one stakeholder defines the specification and a client, whereas another stakeholder provides one or more implementations.

Interfaces, pure abstract classes, traits or function signatures are a realization of this concept in programming languages.

**Embedded C:** This DSL adds interfaces and components to C. Components provide or use one or more interfaces. Different components can be plugged in behind the same interface. In contrast to C++, no runtime polymorphism is supported, the translation to plain C maps method invocation to flat function calls. ◀

**Refrigerators:** Cooling programs can refer to entities defined as

part of the refrigerator hardware as a means of accessing hardware elements (compressors, fans, valves). To enable cooling programs to run with different, but similar hardware configurations, the hardware structure can use "trait inheritance", where a hardware trait defines a set of hardware elements. Other hardware configurations can inherit these traits. As long as cooling programs are only written against traits, they work with any refrigerator that implements the particular set of traits against which the program is written. ◀

*Specialization* Specialization enables one entity to be a more specific variant of another one. Typically, the more specific one can be used in all context where the more general one is valid (Liskov substitution principle<sup>17</sup>). The more general one may be incomplete, requiring the definition of specialized ones that "fill in the holes" left undefined by the more general one. Specialization in the context of DSLs can be used for implementing variants or of evolving a model over time.

**Pension Plans:** The customer had to create a huge set of pension plans, implementing changes in relevant law over time, or for slightly different customer groups. Copying complete plans and then making adaptations was not feasible. Hence the DSL provides a way for pension plans to inherit from one another. Calculation rules can be marked *abstract* (requiring overwriting in sub-plans), *final* rules are not overwritable. Visibility modifiers control which rules are considered "implementation details". ◀

**Refrigerators:** A similar approach is used in the refrigerator DSL. Cooling programs can specialize other cooling programs. Since the programs are fundamentally state-based, we had to define what exactly it means to override a pumping program. ◀

*Types and Instances* Types and instances refers to the ability to define a structure that can be parametrized when it is instantiated.

**Embedded C:** Apart from C's *structs* (which are instantiatable data structures) and components (which can be instantiated and connected), state machines can be instantiated as well. Each instance can be in a different state at any given time. ◀

*Superposition and Aspects* Superposition refers to the ability to merge several model fragments according to some DSL-specific merge operator. Aspects provide a way of "pointing to" several locations in a program based on a pointcut operator (essentially a query over a program or its execution), adapting the model in ways specified by the

<sup>17</sup> B. Liskov and J. M. Wing. A behavioral notion of subtyping. *TOPLAS*, 16(6):1811–1841, 1994

In GPLs, we know this approach from class inheritance. "Leaving holes" is realized by abstract methods.

In programming languages we know this from classes and objects (where constructor parameters are used for parametrization) or from components (where different instances can be connected differently to other instances).

aspect. Both approaches support the creation of many different model variants from the same set of model fragments.

**Embedded C:** This DSL provides a way of advising component definitions, to introduce new ports from within an aspect. This is used, for example, to modularize the Monitoring concern. ◀

**WebDSL:** Entity declarations can be *extended* in separate modules. This makes it possible to declare in one module all data model declarations of a particular feature. For example, in the researchr application, a `Publication` can be `Tagged`, which requires an extension of the `Publication` entity. This extension is defined in the `tag` module, together with the definition of the `Tag` entity. ◀

*Versioning* Often, artifacts within DSL programs tracked over time. One alternative is to simply version the model files using existing version control systems, or the version control mechanism built into the language workbench. However, this requires users to interact with often large and complex version control systems and prevents domain-specific adaptations of the version control approach.

The other alternative is to make versioning and tracking over time a part of the DSL definition. For example, model elements can be tagged with version numbers or specify a revision chain by pointing to a previous version, and enforcing compatibility constraints between those versions. Instead of versions, business data is often time-dependent, where different revisions of a business rule apply to different periods of time. Support for these approaches can be built directly into the DSL, with various levels of tool support.

**Embedded C:** No versioning is integrated into the DSL. Users work with MPS' integration with popular version control systems. ◀

**Component Architecture:** Interfaces can specify a *new version of* reference to another component. If they do so, a constraint enforces that the new version provides at least the same operations, plus optional additional ones, as the old version. *new version of* can also be used among components. In this case, the new version as to have the same (or additional) provided ports with the same interfaces or new versions of these interfaces. It must have the same or fewer required ports. Effectively, this means that the new version of something must be replacement-compatible with the old version. ◀

**Pension Plans:** In the pension workbench, calculation rules have validity dates. This supports the evolution of calculation rules

This is especially important in the context of product line engineering and is discussed in

M. Voelter and E. Visser. Product line engineering using domain-specific languages. In *SPLC*, 2011

over time, while retaining reproducibility for calculations performed at an earlier point in time. Since the Intentional Domain Workbench is a projectional tool, pension plans can be shown with only the version of a rule for a given point in time. ◀

### 1.7.2 Behavior

The behavior description of a DSL must of course be aligned with the needs of the domain. However, in many cases, the behavior required for a domain can be derived from well-known behavior description paradigms, with slight adaptations or enhancements, or simply interacting with domain-specific structures or data. Note also that there are two kinds of DSLs that don't make use of these kinds of behavior descriptions. Some DSLs really just specify structures. Examples include data definition languages or component description languages (although both of them often use expressions for derived data, data validation or pre- and postconditions). Another kind of DSL only specifies the kind of behavior required, and the generator creates the algorithmic implementation. For example, a DSL may specify that the communication between two parts of the system should be asynchronous. The generator then maps this to an implementation that behaves according to this statement.

**Component Architecture:** This component architecture DSL is an example of a structure-only DSL, since it only described black box components and their interfaces and relationships. ◀

In this section, I want to outline some of the most well-known behavioural paradigms that can serve as useful starting points for behaviour descriptions in DSLs.

*Imperative* Imperative programs consist of a sequence of statements, or instructions, that change the state of a program. That state may be local to some kind of module (e.g. a procedure), global or external (when talking to periphery). Procedural and object-oriented programming are both imperative, using different means for structuring and (in case of OO) specialization. Because of the aliasing problem, imperative programs are expensive to analyse. Debugging imperative programs involves stepping through the instructions and watching the state change.

**Embedded C:** Since C is used as a base language, this language is fundamentally imperative. Some of the DSLs on top of it use other paradigms. ◀

**Refrigerators:** The cooling language uses various paradigms, but contains sequences of statements to implement aspects of the over-

This is only an overview over a few paradigms; many more exist. I refer to the excellent Wikipedia entry on *Programming Paradigms* and to the book

P. V. Roy and S. Haridi. *Concepts, Techniques, and Models of Computer Programming*. MIT Press, 2004

For many people, often including domain experts, this approach is most obvious. Hence it is often a good starting point for DSLs.

all cooling behaviour. ◀

*Functional* Functional programming uses the function as the core abstraction. A function's return value can only depend on the values of its parameters. Functions cannot access global state, no side effects are allowed. Calling the same function several times with the same arguments has to return the same value (that value may even be cached!). No aliasing (through mutable memory cells) is supported, because values are immutable once they are created. Since all dependencies of a computed value are local to a function (the arguments), various kinds of analyses are possible. If assignment to variables is supported, then it uses a form where a variable can only be assigned once. To create real-world programs, a purely functional language is usually not sufficient, because it cannot affect the environment. Since there is no state to watch change as the program steps through instructions, debugging can be done by simply showing all intermediate results of all function calls, basically "inspecting" the state of the calculation. This makes building debuggers much simpler. Functional programming is hence often used for certain parts ("calculation core") of a more complex system.

**Pension Plans:** The calculation core of pension rules is functional. Consequently, a debugger has been implemented that, for a given set of input data, shows the rules as a tree where all intermediate results of each function call are shown. No "step through" debugger is necessary. ◀

A relevant subset of functional programming is pure expressions (as in  $3 * 2 + 7 > i$ ). Instead of calling functions, operators are used. However, operators are just inline-notations for function calls. Usually the operators are hard wired into the language, so it is not possible for users to define their own functional abstractions. This is the main differentiator to functional programming in general.

**Component Architecture:** This DSL uses expressions for pre- and post conditions in operations in component interfaces. ◀

**Embedded C:** We use expressions in the guard conditions of the state machine extension. Of course, C's expression language is reused here. ◀

*Declarative* Declarative programming can be considered the opposite of imperative programming (and, to some extent, functional programming). A declarative program does not specify any control flow. It does not specify a set of steps of a calculation. Instead, a declarative program only specifies a what the program should accomplish,

not how. This is often done by specifying a set of properties of the program's goal. Some kind of evaluation engine then tries to find solutions. The particular advantage of this approach is that it is not predefined how a solution is found, the evaluation engine has a lot of freedom in doing so, possibly using different solutions in different environments. This large degree of freedom often makes finding the solution expensive. Debugging declarative programs can be hard since the solution algorithm may be very complex, involve (systematic) trial and error or backtracking, or may not even be known to the user of the language.

Declarative programming has many important subgroups and use cases. For *concurrent programs*, a declarative approach allows the efficient execution of the same program on different parallel hardware. In *constraint programming*, the programmer specifies a constraints between a set of variables. The engine tries to find values for these variables that satisfy all constraints. Solving mathematical equation systems is an example. So is efficient resource allocation in embedded systems. The evaluation engine is often called a solver. .

**Component Architecture:** This DSL specifies timing and resource characteristics for component and interface operations. Based on this data, one could run an algorithm which allocates the component instances to computing hardware so that the hardware is used as efficiently as possible, while at the same time reducing the amount of bus traffic. This is an example of constraint solving. ◀

**Embedded C:** This DSL supports presence conditions for product line engineering. A presence condition is a boolean expression over a set of configuration features that determines whether the associated piece of code is present for a given combination of feature selections. To verify the structural integrity of programs in the face of varying feature combination, constraint programming is used. From the program, the presence conditions and the feature model a set of boolean equations is generated. A solver then makes sure they are consistent by trying to find an example solution that violates the boolean equations. ◀

**Example:** Another example for declarative programming is the type system DSL used by MPS itself. Language developers specify a set of type equations containing free type variables, among other things. A unification engine tries to solve the set of equations by assigning types to the free type variables so that the set of equations is consistent. We describe this approach in detail in section ◀

*Logic programming* is another subparadigm of declarative program-

Examples for boolean constraint programming include the Alloy language or any other SAT solver.

**TODO:** cite: refer to DSL impl chapter, and to literature (Czarnecki)

**TODO:** cite

ming where users specify logic clauses (facts and relations) as well as queries. A theorem prover tries to solve the queries..

The Prolog language works this way

*Reactive/Event-based/Agent* In this paradigm, behavior is triggered based on events received by some entity. Events may be created by another entity or by the environment (or a driver). Reactions are expressed by the production of other events. Events may be globally visible or explicitly routed between entities, possibly using filter and/or using priority queues. This approach is often used in embedded system that have to interact with the real world. The real world produces events as it changes.

A variant of this approach queries the inputs at intervals controlled by a scheduler. The input events may be queued, or they may be considered continuous signals, whose values are queried in scheduled intervals, and output signals are created.

**Refrigerators:** The cooling algorithms are reactive programs that control the cooling hardware based on environment events. Such events include the opening of a refrigerator door, the crossing of a temperature schedule, or a timeout that triggers defrosting of a cooling compartment. Events are queued, and the queues are processed in intervals determined by a scheduler. ◀

Debugging is simple if the timing of input events can be controlled. Visualizing incoming events and the code that is triggered as a reaction is relatively simple. If the timing of input events cannot be controlled, then debugging can be almost impossible, because humans are way too slow to fit "in between" events that may be generated by the environment in rapid succession. For this reason, various kinds of simulators are used to debug the behaviour of reactive systems.

**Refrigerators:** The cooling language comes with a simulator based on an interpreter where the behaviour of a cooling algorithm can be debugged. Events are explicitly created by the user, on a time scale that is compatible with the debugging process. ◀

*Dataflow* The dataflow paradigm is centered around variables with dependencies (relationships in terms of calculation rules) among them. As a variable changes, those that depend on the variable are recalculated. We know this approach mainly from two use cases. One is spreadsheets: cell formulas express dependencies to other cells. As the values in these other cells change, the dependend cells are recalculated. The other use case is data flow (or block) diagrams (Fig. 1.9, used in embedded software, ETL systems and enterprise messaging and CEP. There, the calculations are encapsulated in the blocks, and the lines represent dependencies — the output of one blocks "flows"

into input slot of another block. There are three different execution modes:

- The first one considers the data values as continuous signals. At the time one of the inputs changes, all dependent values are recalculated. The change triggers the recalculation. This is the model used in spreadsheets.
- The second one considers the the data values quantized, unique messages. Only if a message is available for all inputs, a new output message is calculated. The calculation is synchronized on the availability of a message at each input, and upon calculation, these messages are consumed. This approach is often used in ETL and CEP systems.
- The third approach is time triggered. Once again, the inputs are understood to be continuous signals, and a scheduler determines when a new calculation is performed. It also makes sure that the calculation "ripples through from left to right" in the correct order. This model is typically used in embedded systems.

Debugging these kinds of systems is relatively straight forward because the calculation is always in a distinct state. Dependencies and data flow, or the currently active block and the available messages can easily be visualized in the spreadsheet or in the block diagram notation. Note that the calculation rules themselves are considered black boxes here.

*State-based* The state-based paradigm describes a system's behaviour in terms of the states the system can be in, the transitions between these states as well as events that trigger these transitions and actions that are executed as states change. State machines are useful for systematically managing the behavior of an entity. It can also be used to describe valid sequences of events, messages or procedure calls. It can be used in an event-driven mode where incoming events actually trigger transitions and the associated actions. Alternatively a state machine can be run in a timed mode, where a scheduler determines when event queues are checked and processed. Except for possible real-time issues, state machines are easy to debug by highlight the state of queues and the current state.

**Embedded C:** As mentioned before, this language provides an extension that supports directly working with state machines. ◀

**Refrigerators:** The behaviour of cooling programs is fundamentally state driven. A scheduler is used to execute the state machine in regular intervals. Transitions are triggered either by incoming,

Figure 1.9: Graphical Notation for Flow

queued events or by changing property values of hardware elements. Note that this language is a good example where a behavioral paradigm is used without significant alterations, but working with domain-specific data structures: refrigerator hardware and their properties. ◀

State-based behavior description is also interesting because it support model checking: a state chart is verified against a set of specifications. The model checker either determines that the state chart conforms to the specifications or provides a counter example. Specifications express something about sequences of states such as: "it is not possible that two traffic lights show green at the same time" or "whenever a pedestrian presses the *request* button, the pedestrian lights eventually will show green"..

### 1.7.3 Combinations

Many DSLs use combinations of various behavioural and structural paradigms described here. A couple of combinations are very typical:

- a data flow language often uses a functional or importative language to describe the calculation rules that express the dependencies between the variables (the contents of the boxes in data flow diagrams or of cells in spreadsheets)
- state machines use expressions as transition guard conditions, as well as typically an imperative language for expressing the actions that are executed as a state is entered or left, or when a transition is executed.
- reactive programming, where "black boxes" react to events, often use data flow or state-based programming to implement the behaviour that determines the reactions.
- in purely structural languages, for example, those for expressing components and their dependencies, a functional language is often used to express pre- and postconditions for operations. A state-based language is often used for protocol state machines, which determines the valid order of incoming events or operation calls.

A good introduction to model checking can be found in [1]. We elaborate on model checking in section 2.1.

Some of the case studies used in this section of the book also use combinations of several paradigms.

**Pension Plans:** The pension language uses functional abstractions with mathematical symbols for the core actuary mathematics. A functional language with a normal textual syntax is used for the higher-level pension calculation rules. A spreadsheet/data flow language is used for expressing unit tests for pension rules. Various nested levels of namespaces are used to organize the rules,

the most important of which is the pension plan. It contains rules and test cases for those rules. Pension plans can inherit from other plans as a means of expressing variants. Rules are versioned over time, and the actual calculation formula is part of the version. Thus, a pension plan's behaviour can be made to be different for different points in time. Rules in a sub-plan can override rules in the plan from which the sub-plan inherits. Plans can be declared to be abstract, with abstract rules that have to be implemented in sub-plans. ◀

**Refrigerators:** The cooling behavior is a reactive system. Events are produced by hardware elements (and their drivers). A state machine constitutes the top level structure. Within it, an imperative language is used. Programs can inherit from another program, overwriting states defined in the base program. New transitions can be added, and the existing transitions can be overridden. This way, an extended program can "plug into" the base program. ◀

## 1.8 Language Modularity

Reuse of modularized parts makes software development more efficient, since similar functionality does not have to be developed over and over again. A similar argument can be made for languages. Being able to reuse languages in new contexts make designing DSLs more efficient.

We have identified the following four: referencing, extension, reuse and embedding. We distinguish them regarding fragment structure and language dependencies, as illustrated in Fig. 1.10. Fig. 1.11 shows the relationships between fragments and languages in these cases. We consider these two criteria to be essential for the following reasons.

*Language dependencies* capture whether a language has to be designed with knowledge about a particular composition partner in mind in order to be composable with that partner. It is desirable in many scenarios that languages be composable *without* previous knowledge about all possible composition partners. *Fragment Structure* captures whether the two composed languages can be syntactically mixed. Since modular concrete syntax can be a challenge, this is not always that possible, though often desirable.

Note how this observation leads to the desire to better modularize and reuse some of the above paradigms. Room for research :-)

Language modularization and reuse is often not driven by end user or domain requirements, but rather, by a desire of the language designers and implementers for consistency and avoidance of duplicate implementation work.

### 1.8.1 Language Referencing

Language referencing (Fig. 1.12) enables *homogeneous* fragments with cross-references among them, using *dependent* languages.

A fragment  $f_2$  depends on  $f_1$ .  $f_2$  and  $f_1$  are expressed with different languages  $l_2$  and  $l_1$ . The referencing language  $l_2$  depends on the referenced language  $l_1$  because at least one concept in the  $l_2$  references a concept from  $l_1$ . We call  $l_2$  the *referencing* language, and  $l_1$  the *referenced* language. While equations (2) and (3) continue to hold, (1) does not. Instead

$$\forall r \in \text{Refs}_{l_2} \mid lo(r.\text{from}) = l_2 \wedge lo(r.\text{to}) = (l_1 \vee l_2) \quad (1.8)$$

(we use  $x = (a \vee b)$  as a shorthand for  $x = a \vee x = b$ ).

Figure 1.10: We distinguish the four modularization and composition approaches regarding their consequences for fragment structure and language dependencies.

*Viewpoints* As we have discussed before, a domain  $D$  can be composed from different concerns. One way of dealing with this is to define a separate concern-specific DSLs, each addressing one or more of the domain's concerns. A program then consists of a set of concern-specific fragments, that relate to each other in a well-defined way using language referencing. The latter approach has the advantage that different stakeholders can modify "their" concern independent of others. It also allows reuse of the independent fragments and languages with different referencing languages. The obvious drawback is that for tightly integrated concerns the separation into separate fragments can be a usability problem.

**Refrigerators:** As an example, consider the domain of refrigerator configuration. The domain consists of four concerns. The first concern  $H$  describes the hardware structure of refrigerators appliances including compartments, compressors, fans, vents and thermometers. The second concern  $A$  describes the cooling algorithm using a state-based, asynchronous language. Cooling programs refer to hardware building blocks and access the their properties in expressions and commands. The third concern is testing  $T$ . A cooling test can test and simulate cooling programs. The

fourth concern  $P$  is parametrization, used to configure a specific hardware and algorithm with different settings, such as the actual target cooling temperature. The dependencies are as follows:  $A \rightarrow H, T \rightarrow A, P \rightarrow A$ . Each of these concerns are implemented as a separate language with references between them.  $H$  and  $A$  are separated because  $H$  is defined by product management, whereas  $A$  is defined by thermodynamicists. Also, several algorithms for the same hardware must be supported, which makes separate fragments for  $H$  and  $A$  useful.  $T$  is separate from  $A$  because tests are not strictly part of the product definition and may be enhanced after a product has been released. Finally,  $P$  is separate, because the parameters have to be changed by technicians in the field, and several parametrizations for the same algorithm exist. These languages have been built as part of a single project, so the dependencies between them are not a problem. ◀

Referencing implies knowledge about the relationships of the languages as they are designed. Viewpoints are the classical case for this. The dependent languages *cannot* be reused, because of the dependency on the other language.

*Progressive Refinement* Progressive refinement, also introduced earlier, also makes use of language referencing.

### 1.8.2 Language Extension

Language extension Fig. 1.12 enables *heterogeneous* fragments with *dependent* languages. A language  $l_2$  extending  $l_1$  adds additional language concepts to those of  $l_1$ . We call  $l_2$  the *extending* language, and  $l_1$  the *base* language. To allow the new concepts to be used in the context provided by  $l_1$ , some of them extend concepts in  $l_1$ . So, while  $l_1$  remains independent,  $l_2$  becomes dependent on  $l_1$  since

$$\exists i \in \text{Inh}(l_2) \mid i.\text{sub} = l_2 \wedge i.\text{super} = l_1 \quad (1.9)$$

Consequently, a fragment  $f$  contains language concepts from both  $l_1$  and  $l_2$ :

$$\forall e \in E_f \mid lo(e) = (l_1 \vee l_2) \quad (1.10)$$

In other words,  $C_f \subset (C_{l_1} \cup C_{l_2})$ , so  $f$  is *heterogeneous*. For heterogeneous fragments (3) does not hold anymore, since

$$\begin{aligned} \forall c \in \text{Cdn}_f \mid lo(\text{co}(c.\text{parent})) &= (l_1 \vee l_2) \wedge \\ lo(\text{co}(c.\text{child})) &= (l_1 \vee l_2) \end{aligned} \quad (1.11)$$

Language extension fits well with the hierarchical domains: a language  $L_B$  for a domain  $D$  may extend a language  $L_A$  for  $D_{-1}$ .  $L_B$

Note that copying a Language definition and changing it does not constitute a case of language extension, because the extension is not modular, it is invasive. Also, a native interfaces that support calling one language from another one (like calling C from Perl or Java) is not language extension; rather it is a form of language referencing. The fragments remain homogeneous.

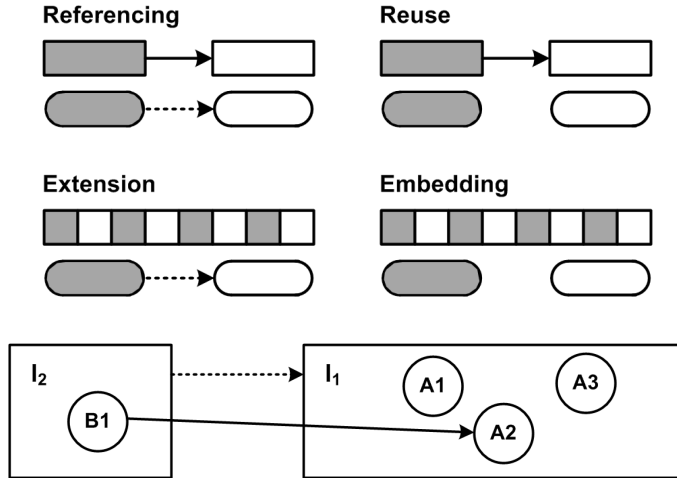

Figure 1.11: The relationships between fragments and languages in the four composition approaches. Boxes represent fragments, rounded boxes are languages. Dotted lines are dependencies, solid lines references/associations. The shading of the boxes represent the two different languages.

Figure 1.12: Referencing: Language  $l_2$  depends on  $l_1$ , because concepts in  $l_2$  reference concepts in  $l_1$ . (We use rectangles for languages, circles for language concepts, and UML syntax for the lines: dotted = dependency, normal arrows = associations, hollow-triangle-arrow for inheritance.)

contains concepts specific to  $D$ , making analysis and transformation of those concepts possible without pattern matching and semantics recovery. As explained in the introduction, the new concepts are often reified from the idioms and patterns used when using an  $L_A$  for  $D$ . Language semantics are typically defined by mapping the new abstractions to just these idioms (see Section 1.4) *inline*. This process, also known as *assimilation*, transforms a heterogeneous fragment (expressed in  $L_D$  and  $L_{D+1}$ ) into a homogeneous fragment expressed only with  $L_D$ .

Figure 1.13: Extension:  $l_2$  extends  $l_1$ . It provides additional concepts  $B3$  and  $B4$ .  $B3$  extends  $A3$ , so it can be used as a child of  $A2$ , plugging  $l_2$  into the context provided by  $l_1$ . Consequently,  $l_2$  depends on  $l_1$ .

**Embedded C:** As an example consider embedded programming. The C programming language is typically used as the GPL for  $D_0$  in this case. Extensions for embedded programming include state machines, tasks or data types with physical units. Language extensions for the subdomain of real-time systems may include ways of specifying deterministic scheduling and worst-case execution time. For the avionics subdomain support for remote communication using some of the bus systems used in avionics could be added. ◀

Defining a  $D$  languages as an extension of a  $D_{-1}$  language can also

Language extension is especially interesting if  $D_0$  languages are extended, making a DSL an extension of a general purpose language.

have drawbacks. The language is tightly bound to the  $D_{-1}$  language it is extended from. While it is possible for a standalone DSL in  $D$  to generate implementations for different  $D_{-1}$  languages, this is not easily possible for DSLs that are extensions of a  $D_{-1}$  language. Also, interaction with the  $D_{-1}$  language may make meaningful semantic analysis of complete programs (using  $L_D$  and  $L_{D-1}$  concepts) hard. This problem can be limited if isolated  $L_D$  sections are used, in which interaction with  $L_{D-1}$  concepts is limited and well-defined.

Extension is especially useful for bottom-up domains. The common patterns and idioms identified for a domain can be reified directly into linguistic abstractions, and used directly in the language from which they have been embedded. Incomplete languages are not a problem, since users can easily fall back to  $D_{-1}$  to implement the rest. Since DSL users see the  $D_{-1}$  code all the time anyway, they will be comfortable falling back to  $D_{-1}$  in exceptional cases. This makes extensions suitable only for DSLs used by developers. Domain expert DSLs are typically not implemented as extensions.

*Restriction* Sometimes language extension is also used to *restrict* the set of language constructs available in the subdomain. For example, the real-time extensions for C may restrict the use of dynamic memory allocation, the extension for safety-critical systems may prevent the use of void pointers and certain casts. Although the extending language is in some sense smaller than the extended one, we still consider this a case of language extension, for two reasons. First, the restrictions are often implemented by *adding additional* constraints that report errors if the restricted language constructs are used. Second, a marker concept may be added to the base language. The restriction rules are then enforced for children of these marker concepts (e.g. in a module marked as "safe", one cannot use void pointers and the prohibited casts).

### 1.8.3 Language Reuse

Language reuse (Fig. 1.14) enables *homogenous* fragments with *independent* languages. Given are two independent languages  $l_2$  and  $l_1$  and two fragment  $f_2$  and  $f_1$ .  $f_2$  depends on  $f_1$ , so that

$$\begin{aligned} \exists r \in \text{Refs}_{f_2} \mid fo(r.\text{from}) = f_2 \wedge \\ fo(r.\text{to}) = (f_1 \vee f_2) \end{aligned} \quad (1.12)$$

Since  $l_2$  is independent, it cannot directly reference concepts in  $l_1$ . This makes  $l_2$  reusable with different languages (in contrast to language referencing, where concepts in  $l_2$  reference concepts in  $l_1$ ). We call  $l_2$  the *context* language and  $l_1$  the *reused* language.

One way of realizing dependent fragments while retaining independent languages is using an adapter language  $l_A$  where  $l_A$  *extends*

TODO: cite Models Paper

$l_2$  and

$$\exists r \in \text{Refs}_{l_A} \mid lo(r.\text{from}) = l_A \wedge lo(r.\text{to}) = l_1 \quad (1.13)$$

Language referencing supports reuse of the referenced language. Language reuse supports the reuse of the *referencing* language as well. Consider as examples a language for describing user interfaces. It provides language concepts for various widgets, layout definition and disable/enable strategies. It also supports data binding, where data structures are associated with widgets, to enable two-way synchronization between the UI and the data. Using language reuse, the same UI language can be used with different data description languages. Referencing is not enough because the UI language would have a direct dependency on a particular data description language. Changing the dependency direction to  $data \rightarrow ui$  doesn't solve the problem either, because this would go against the generally accepted idiom that UI has dependencies to the data, but not vice versa (cf. the MVC pattern).

Generally, the referencing language is built with the knowledge that it will be reused with other languages, so hooks may be provided for adapter languages to plug in. The UI language thus may define an abstract concept `DataMapping` which is then extended by various adapter languages.

Reuse supports the case where all participating languages have no dependencies on the other languages and can be reused independently. This makes sense for concern DSLs that have the potential to be reused in many domains, with minor adjustments. Examples include role-based access control, relational database mappings.

#### 1.8.4 Language Embedding

Language embedding (Fig. 1.15) enables *heterogeneous* fragments with *independent* languages. It is similar to reuse in that there are two independent languages  $l_1$  and  $l_2$ , but instead of establishing references between two homogeneous fragments, we now embed instances of concepts from  $l_2$  in a fragment  $f$  expressed with  $l_1$ , so

$$\begin{aligned} \forall c \in \text{Cdn}_f \mid lo(co(c.\text{parent})) = l_1 \wedge \\ lo(co(c.\text{child})) = (l_1 \vee l_2) \end{aligned} \quad (1.14)$$

Unlike language extension, where  $l_2$  depends on  $l_1$  because concepts in  $l_2$  extends concepts in  $l_1$ , there is no such dependency in this case. Both languages are independent. We call  $l_2$  the *embedded* language and  $l_1$  the *host* language. Again, an adapter language  $l_A$  that extends  $l_1$  can be used to achieve this, where

$$\exists c \in \text{Cdn}_{l_A} \mid lo(c.\text{parent}) = l_A \wedge lo(c.\text{child}) = l_1 \quad (1.15)$$

One could argue that in this case reuse is just a clever combination of referencing and extension. While this is true from an implementation perspective, it is worth describing as a separate approach, because it enables the combination of two *independent languages* by adding an adapter *after the fact*, so no pre-planning during the design of  $l_1$  and  $l_2$  is necessary.

Embedding supports syntactic composition of independently developed languages. As an example, consider a state machine language that can be combined with any number of programming languages such as Java or C. If the state machine language is used together with Java, then the guard conditions used in the transitions should be Java expressions. If it is used with C, then the expressions should be C expressions. The two expression languages, or in fact, any other one, must be embeddable in the transitions. So the state machine language cannot depend on any particular expression language, and the expression languages of C or Java obviously cannot be designed with knowledge about the state machine language. Both have to remain independent, and have to be embedded using an adapter language.

When embedding a language, the embedded language must often be extended as well. In the above example, new kinds of expressions must be added to support referencing event parameters. These additional expressions will typically reside in the adapter language as well.

Figure 1.14: Reuse:  $l_1$  and  $l_2$  are independent languages. Within an  $l_2$  fragment, we still want to be able to reference concepts in another fragment expressed with  $l_1$ . To do this, an adapter language  $l_A$  is added that depends on both  $l_1$  and  $l_2$ , using inheritance and referencing to adapt  $l_1$  to  $l_2$ .

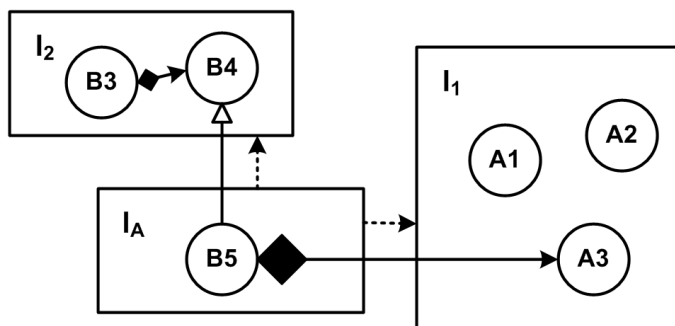

Figure 1.15: Embedding:  $l_1$  and  $l_2$  are independent languages. However, we still want to use them in the same fragment. To enable this, an adapter language  $l_A$  is added. It depends on both  $l_1$  and  $l_2$ , and uses inheritance and composition to adapt  $l_1$  to  $l_2$  (this is the almost the same structure as in the case of reuse; the difference is that  $B5$  now contains  $A3$ , instead of just referencing it.)

**WebDSL:** In order to support queries over persistent data, WebDSL embeds the Hibernate Query Language (HQL) such that HQL

queries can be used as expressions. Queries can refer to entity declarations in the program and to variables in the scope of the query. ◀

**Pension Plans:** The pension workbench DSL embeds a spreadsheet language for expressing unit tests for pension plan calculation rules. ◀

*Cross-Cutting Embedding, Metadata* A special case of embedding is handling meta data. We define meta data as program elements that are not essential to the semantics of the program, and are typically not handled by the primary model processor. Nonetheless these data need to be related to program elements, and, at least from a user's perspective, they need to be embedded in programs. Since most of them are rather generic, embedding is the right composition mechanism: no dependency to any specific language should be necessary, and the meta data should be embeddable in any language. Example meta data includes:

*Documentation* should be attachable to any program element, and in the documentation text, other program elements should be referencable.

*Traces* capture typed relationships between program elements or between program elements and requirements or other documentation ("this element *implements* that requirement")

*Presence Conditions* in product line engineering describe whether a program element should be available in the program for a given product configuration ("this procedure is only in the program in the *international* variant of the product").

In projectional editors, this meta data can be stored in the program tree, and shown only if switched on. In textual editors, meta data is often stored in separate files, using pointers to refer to the respective model elements. The data may be shown in hovers or views adjacent to the editor itself.

### 1.8.5 *Implementation Challenges and Solutions*

*Syntax* Referencing and Reuse keeps fragments homogeneous. Mixing of concrete syntax is not required. A reference between fragments is usually simply an identifier and does not have its own internal structure for which a grammar would be required. The name resolution phase can then create the actual cross-reference between abstract syntax objects. In the refrigerator example, the algorithm language contains cross-references into the hardware language. Those references

are simple, dotted names (*a.b.c*). In the UI example, the adapter language simply introduces dotted names to refer to fields of data structures.

Extension and Embedding requires modular concrete syntax definitions because additional language elements must be "mixed" with programs written with the base language. In the embedded programming example, state machines are hosted in regular C programs. This works because the C language's `Module` construct contains a collection of `ModuleContents`, and the `StateMachine` concept extends the `ModuleContent` concept. This state machine language is designed specifically for being embedded into C, so it can access and extend the `ModuleContent` concept. If the state machine language were reusable with any host language in addition to C, then an adapter language would provide a language concept that adapts C's `IModuleContent` to `StateMachine`, because `StateMachine` cannot directly extend `IModuleContent` — it does now depend on the C language.

*Type Systems* For referencing, the type system rules and constraints of the referencing language typically have to take into account the referenced language. Since the referenced language is known when developing the referencing language, the type system can be implemented with the referenced language in mind as well. In the refrigerator example, the algorithm language defines typing rules for hardware elements (from the hardware language), because these types are used to determine which properties can be accessed on the hardware elements (e.g. a compressor has a property `active` that controls if it is turned on or off).

In case of extension, the type systems of the base language must be designed in a way that allows adding new typing rules in language extensions. For example, if the base language defines typing rules for binary operators, and the extension language defines new types, then those typing rules may have to be overridden to allow the use of existing operators with the new types. In the embedded systems example, a language extension provides types with physical units (as in 100 kg). Additional typing rules are needed to override the typing rules for C's basic operators (+, -, \*, /, etc.).

For reuse and embedding, the typing rules that affect the interplay between the two languages reside in the adapter language. In the UI example the adapter language will have to adapt the data types of the fields in the data description to the types the UI widgets expect. For example, a combo box widget can only be bound to fields that have some kind of text or enum data type. Since the specific types are specific to the data description language (which is unknown at the time of creation of the UI language), a mapping must be provided in

the adapter language.

*Transformation* In this section we use the terms *transformation* and *generation* interchangeably. In general, the term transformation is used if one tree of program elements is mapped to another tree, while generation describes the case of creating text from program trees. However, for the discussions in this section, this distinction is generally not relevant.

Three cases have to be considered for referencing. The first one (Fig. 1.16) propagates the referencing structure to two independent target fragments. We call these two transformations single-sourced, since each of them only uses a single, homogeneous fragment as input and creates a single, homogeneous fragment, perhaps with references between them. Since the referencing language is created with the knowledge about the referenced language, the generator for the referencing language can be written with knowledge about the names of the elements that have to be referenced in the other fragment. If a generator for the referenced language already exists, it can be reused unchanged. The two generators basically share naming information.

**Refrigerators:** The refrigerator example uses this case. From the hardware description we generate an XML file that configures a framework that actually collects the data behind the properties of the hardware components in the running refrigerator. The C code generated from the algorithm accesses that framework, using agreed-upon identifiers to identify properties whose value have to be read or set. ◀

The second case (Fig. 1.17) is a multi-sourced transformation that creates one single homogeneous fragment. This typically occurs if the referencing fragment is used to guide the transformation of the referenced fragment, for example by specifying target transformation strategies. In this case, a new transformation has to be written that takes the referencing fragment into account. The possibly existing generator for the referenced language cannot be reused as is. An alternative to rewriting the generator is the use of a preprocessing transformation (Fig. 1.18), that changes the referenced fragment in a way consistent with what the referenced fragment prescribes. The existing transformations for the referenced fragment can then be reused.

AS WE HAVE DISCUSSED ABOVE, language extensions are usually created by defining linguistic abstractions for common idioms of a domain  $D$ . A generator for the new language concepts can simply recreate those idioms when mapping  $L_D$  to  $L_{D-1}$ , a process called assimilation. In other words, transformations for language extensions map

Note that if the state machine language is specifically built to "embed" C expressions, then this is a case of Language Extension, since the state machine language depends on the C expression language.

Figure 1.16: Referencing: Two separate, dependent, single-source transformations

a heterogeneous fragment (containing  $L_{D-1}$  and  $L_D$  code) to a homogeneous fragment that contains only  $L_{D-1}$  code (Fig. 1.19). In some cases additional files may be generated, often configuration files. In the embedded systems state machines example, the state machines are generated down to a function that contains a switch/case statement, as well as enums for states and events.

Sometimes a language extension requires rewriting transformations defined by the base language. For example, in the data-types-with-physical-units example, the language also provides range checking and overflow detection. So if two such quantities are added, the addition is transformed into a call to a special add function instead of using the regular plus operator. This function performs overflow checking and addition.

Language Extension introduces the risk of semantic interactions. The transformations associated with several independently developed extensions of the same base language may interact with each other. Consider the (somewhat constructed) example of two extensions to Java that each define a new statement. When assimilated to pure Java, both new statements require the surrounding Java class to extend a specific, but different base class. This won't work because a Java class can only extend one base class. Interactions may also be more subtle and affect memory usage or execution performance. Note that this problem is not specific to languages, it can occur whenever several independent extensions of a base concept can be used together, ad hoc. To avoid the problem, transformations should be built in a way so that they do not "consume scarce resources" such as inheritance links. A more thorough discussion of the problem of semantic interactions is beyond the scope of this paper, and we refer to <sup>18</sup> for details.

IN THE REUSE SCENARIO, it is likely that both the reused and the context language already come with their own generators. If these generators transform to different, incompatible target languages, no reuse is possible. If they transform to a common target languages (such as Java or C) then the potential for reusing previously existing transformations exists.

There are three cases to consider. The first one, illustrated in Fig. 1.20, describes the case where there is an existing transformation for the reused fragment and an existing transformation for the context fragment — the latter being written with the knowledge that later extension will be necessary. In this case, the generator for the adapter language may "fill in the holes" left by the reusable generator for the referencing language. For example, the generator of the context language may generate a class with abstract methods; the adapter may generate a subclass and implement these abstract methods.

Figure 1.17: A single multi-sourced transformation.

Figure 1.18: A preprocessing transformation that changes the referenced fragment in a way specified by the referencing fragment

Figure 1.19: Extension: transformation usually happens by assimilation, i.e. generating code in the host language from code expressed in the extension language. Optionally, additional files are generated, often some configuration files.

In the second case, Fig. 1.21, the existing generator for the reused fragment has to be enhanced with transformation code specific to the context language. In this case, a mechanism for composing transformations is needed.

The third case, Fig. 1.22, leaves composition to the target languages. We generate three different independent, homogeneous fragments, and a some kind of weaver composes them into one final, heterogeneous artifact. Often, the weaving specification is the intermediate result generated from the adapter language. An example implementation could use AspectJ.

*Embedding* An embeddable language may not come with its own generator, since, at the time of implementing the embeddable language, one cannot know what to generate. In that case, when embedding the language, a suitable generator has to be developed. It will typically either generate host language code (similar to generators in the case of language extension) or directly generate to the same target language that is generated to by the host language.

If the embeddable language comes with a generator that transforms to the same target language as the embedding language, then the generator for the adapter language can coordinate the two, and make sure a single, consistent fragment is generated. Fig. 1.23 illustrates this case.

Just a language extension, language embedding may also lead to semantic interactions if multiple languages are embedded into the same host language.

### 1.8.6 Tool Support

*Eclipse Xtext* Regarding syntax, language referencing is supported by Xtext. The grammar language comes with special support to reference concepts defined in other languages (or Ecore-based meta model in general). Language extension is also supported, but for at most one base language. Consequently, language reuse is possible as well. However language embedding is not supported because of the limitation to extend only one other language.

Constraints are implemented in Xtext as Java methods that query the AST and report errors. Xtext does not directly support a concise definition of type systems, but third party solutions exist, (e.g. the Xtext Typesystem Framework<sup>19</sup>. Xtext also comes with XBase, a reusable expression language. Languages can extend Xbase to reuse these expressions. Xbase comes with a framework for type calculations. This framework can be extended in a principled way to integrate the typing rules of a language that extends XBase.

Xtext comes with a transformation and code generation language called Xtend. It supports dependency injection as a first class citizen.

Figure 1.20: Reuse: Reuse of existing transformations for both fragments plus generation of adapter code

Figure 1.21: Reuse: composing transformations

Figure 1.22: Reuse: generating separate artifacts plus a weaving specification

Figure 1.23: In transforming embedded languages, a new transformation has to be written if the embedded language does not come with a transformation for the target language of the host language

This makes it possible to override parts of generators selectively, if the original generator developer has delegated the relevant parts to injected classes. This facility supports the transformation challenges outlined in the previous section nicely.

*JetBrains MPS* MPS supports syntax composition. Since no grammar is used, the extending language simply creates new language constructs, some of them extending concepts from the base language. In cases where ambiguity would arise in a grammar-based system, MPS requires the language user to decide during input which of the alternatives should be used. A language in MPS can extend any number of languages. In particular, for a given base language, a program can be written using any number of languages extending this base language, without first defining a composed language explicitly. For example, a set of extensions to C can be developed independently, and users can then decide ad hoc which extensions to use in a program (as long as the extensions are semantically compatible). From a syntactic perspective, all LMR&C approaches are supported by MPS without any limits.

MPS also supports restriction. A language concept can restrict under which parents it can be used, or which children a concept may have. These constraints literally remove the ability to enter constructs that would violate the constraints. Using this approach, the unit testing extension to C enforces that assert statements can only be used in unit tests and not in any other statement list.

MPS has another approach for language embedding called *attributes*. An attribute introduces additional parent-child relationships into concepts defined in other languages, without invasively changing the definition of that other language. By making an attribute apply to `BaseConcept`, the super concept of all concepts (comparable to `java.lang.Object`), attributes can be made applicable to arbitrary program elements, effectively supporting AOP-like introductions on language level. Attributes are typically used for adding "meta data" such as documentation, presence conditions in product line engineering or requirements traces.

MPS comes with a DSL for expressing type system rules. It is based on a unification engine and supports type inference. For typing rules that should be extensible, MPS supports so-called overloaded operation containers. This mechanism supports plugging in additional typing rules by adding them to the language definition. For example, the typing rules for binary operators in C are implemented this way. The language extension that adds types with physical units provides additional typing rules for the case when the left and/or right argument of a binary operator is a type with a physical unit.

Regarding transformations, MPS distinguishes two cases. The first

<sup>19</sup> <http://code.google.com/a/eclipselabs.org/p/xtext-typesystem/>

one covers text generation. Text generators are relatively inflexible regarding modularization, but they are used only for the lowest level languages (typically GPLs covering  $D_0$  such as Java or C). All other "generations" happens by transformation rules that work on the projected tree, typically using assimilation. For example, the concepts in a state machine extension to C are transformed back to the concepts in the C language it extends. Overwriting existing generators is also possible by modularizing generators in a suitable way and then using generator priorities to make the overriding generator run before the overridden one. It is also possible to define hooks in generators by generating output elements whose only purpose is to be transformed further by subsequent generators. By plugging in different subsequent generators, the same hook can be transformed into different end results.

Note that MPS does not provide support for systematically handling semantic interactions. Transformations will just fail in case an unintended interaction occurs. To avoid this, transformations have to be designed carefully. Note that a simple approach to lessening the problem would be to be able to declare a language as being *incompatible* with another one. In that case an error could be reported as soon as the languages are used together in a fragment.

*SDF/Spoofax* Syntax definition in Spoofax is based on the SDF2 Syntax Definition Formalism<sup>20</sup>. Since SDF uses the Scannerless Generalized-LR parsing algorithm, the full class of context-free grammars is supported, which is the only grammar class closed under composition, unlike the restricted grammar classes of other parser generators. Furthermore, the parser does not use a separate lexical analysis phase, but rather considers individual tokens as characters, which entails that it supports combination of languages with a different lexical syntax, as demonstrated, for example, in the syntax definition for AspectJ<sup>21</sup>. Thus, SDF supports both extension and embedding of languages.

Semantic analysis, transformation, and code generation in Spoofax are defined with the Stratego transformation language<sup>22</sup>, which is based on the paradigm of term rewriting with programmable strategies. Basic transformations are defined with rewrite rules and can be combined into composite transformations using strategies. Thus, basic rules defining type analysis, static semantic constraints, desugarings, and other transformations for separate language components can be composed into transformations for language compositions. Stratego provides aspects for overriding and adapting transformation strategy definitions<sup>23</sup>.

## 1.9 Concrete Syntax

A good choice of concrete syntax is important for DSLs to be accepted by the intended users, particularly if the users are not programmers. Especially (but not exclusively) in business domains, a DSL will only be successful if and when it uses notations that directly fit the domain — there might even be existing notations you can reuse. A good notation makes expression of common concerns simple and concise and provides sensible defaults. It is ok for less common concerns to require a bit more verbosity in the notation.

There are a couple of major classes for DSL concrete syntax<sup>24</sup>: *Textual* DSLs use traditional ASCII or Unicode text. They basically look and feel like traditional programming languages. *Symbolic* DSLs are textual DSLs with an extended set of symbols, such as fraction bars, mathematical symbols or subscript and superscript. *Graphical* DSLs use graphical shapes. An important subgroup is represented by those that use box-and-line diagrams that look and feel like UML class diagrams or state machines. However, there are more options for graphical notations, such as those illustrated by UML timing diagrams or sequence diagrams. *Tables and Matrices* are a powerful way to represent certain kinds of data and can play an important part for DSLs.

*When to use which form* We do not want to make this section a complete discussion between graphical and textual DSLs — a discussion, that is often heavily biased by previous experience, prejudice and tool capabilities. Here are some rules of thumb. Purely textual DSLs integrate very well with existing development infrastructures, making their adoption relatively easy. They are very well suited for detailed descriptions, anything that is algorithmic or generally resembles (traditional) program source code. Symbolic notations can be considered "better textual", and lend themselves to domains that make heavy use of symbols and special notations. Graphical notations are very good for describing relationships, flow or timing and causal relationships. Finally, tables are very useful for collections of similarly structured data items, or for expressing how two independent dimensions of data relate.

**Pension Plans:** The pension DSL uses mathematical symbols and notations to express insurance mathematics. A table notation is embedded to express unit tests for the pension plan calculation rules. A graphical projection shows dependencies and specialization relationships between plans. ◀

Selection of concrete syntax is simple for domain user DSLs if there is an established notation in the domain already. The challenge then

23

<sup>24</sup> Sometimes form-based GUIs or trees views are considered DSLs. We disagree, because this would make any GUI application a DSL.

The Fortress programming language is close to this.

G. L. S. Jr. Parallel programming and parallel abstractions in fortress. In *IEEEpact*, page 157, 2005

The perfect DSL tool should support freely combining and integrating the various classes of concrete syntax, and be able to show (aspects of) the same model in different notations. As a consequence of tool limitations, this is not always possible, however. The requirements for concrete syntax are a major driver in tool selection.

Figure 1.24: Graphical Notation for Relationships

is to replicate it as closely as possible with the DSL, while cleaning up possible inconsistencies in the notation (since it had not been used formally before). I like to use the term "strongly typed word".<sup>25</sup>

For DSLs targeted at developers, a textual notation is usually a good starting point, since developers are used working with text, and very productive. Tree views, and specific visualizations are often useful, but for editing, a textual notation is a good starting point. It also integrates well with existing development infrastructures.

There are very few DSLs where a purely graphical notation makes sense. In most cases, textual languages are embedded in the diagrams: state machines have expressions embedded the guards and statements in the actions; component diagrams use text for specifications of operations in interfaces, maybe even with expressions for preconditions; block diagrams use a textual syntax for the implementation/parametrization of the blocks. A text box without language support should only be used as a last resort. We suggest using a textual notation, with additional graphical visualizations.

Also note that initially, domain users prefer a graphical notation, because things that are described graphically are easier to comprehend than textual descriptions, right? Not really. What is most important regarding comprehensibility is the alignment of the concepts that need to be conveyed with the abstractions in the language. A well-designed textual notation can go a long way. Also, textual languages are more productive once the learning curve has been passed.

**Multiple Notations** For projectional editors it is possible to define several notations for the same abstract syntax. By changing the projection rules, existing programs can be shown in a different way. This removes some of the burden of getting it right initially, because the notation can be adapted after the fact. Also, for textual notations it is possible to automatically derive graphical visualizations as a way of illustrating key relationships between program elements. In general, for the concrete syntax of a DSL writability is often more important than readability, because additional read-only representations can always be derived automatically.

**Embedded C:** The primary syntax is textual. However, for state machines, tabular notations are supported as well. The projection can be changed as the program is edited, rendering the same state machine textually or as a table. Graphical notations will be added in the future. ◀

**Refrigerators:** The refrigerator DSL uses graphical visualizations to render diagrams of the hardware structure, as well as a graphical state charts representing the underlying state machine. ◀

Figure 1.25: Graphical Notation for Flow

Figure 1.26: Graphical Notation for Causality and Timing

<sup>25</sup> In some cases it is useful to come up with a better notation than the one used historically. This is especially true if the historic notation is Excel :-)

*Relationship to Hierarchical Domains* Domains at low  $D$  are most likely best expressed with a textual or symbolic concrete syntax. Obvious examples include programming languages at  $D_0$ . Mathematical expressions, which are also very dense and algorithmic, use a symbolic notation. As we progress to higher  $D$ s, the concepts become more and more abstract, and as state machines and block diagrams illustrate, graphical notations become useful. However, these two notations are also a good example of language embedding since both of them require expressions: state machines in guards, and block diagrams as the implementation of blocks. Reusable expression languages should be embedded into the graphical notations. Tool support for the integration of graphical and textual concrete syntaxes, including IDE support, become necessary. In case this is not supported by the tool, viewpoints may be an option. One viewpoint could use a graphical notation to define coarse-grained structures, and a second viewpoint uses a textual notation to provide "implementation details" for the structures defined by the graphical viewpoint<sup>26</sup>.

**Embedded C:** The state machine extension of C will be supplanted with a graphical notation later this year. The C expression language that is used in guard conditions for transitions will be usable as labels on the transition arrows. In the table notation for state machines, C expressions can be embedded in the cells as well. ◀

**TODO:** Show integration with graphics and table

## 2

# *Process Issues*

Software development with DSLs requires a compatible development process. A lot of what's required is similar to what's required for any other reusable artifact such as a framework. A workable process must be established between those who build the reusable artifact and those who use it. Requirements have to flow in one direction, and a finished, stable, tested and document tool in the other. Also, using DSLs is a bit of a change for all involved, especially the domain experts. In this chapter we provide some guidelines.

### 2.1 *DSL Development*

#### 2.1.1 *Requirements for the Language*

How do you find out what your DSL should express? What are the relevant abstractions and notations? This is a non-trivial issue, in fact, it is one of the key issues in using DSLs. It requires a lot of domain expertise, thought and iteration. The core problem is that you're trying to not just understand one problem, but rather a *class* of problems. Understanding and defining the extent and nature of this class of problems can be non-trivial. There are several typical ways of how to get started.

If you're building a technical DSL, the source for a language is often an existing framework, library, architecture or architectural pattern. The knowledge often already exists, and building the DSL is mainly about formalizing the knowledge: defining a notation, putting it into a formal language, and building generators to generate parts of the (potentially complex) implementation code. In the process, you often also want to put in place reasonable defaults for some of the framework features, thereby increasing the level of abstraction and making framework use easier.

In case of business domain DSLs, you can often mine the existing (tacit) knowledge of domain experts. In domains like insurance, science or logistics, domain experts are absolutely capable of precisely expressing domain knowledge. They do it all the time, often using Excel or Word. They often have a "language" to express domain concerns, although it is usually not formal, and there's no tool support. In this context, your job is to provide formality and tooling. Similar to domain knowledge, other domain artifacts can also be exploited: for example, hardware structures or device features are good candidates for abstractions in the respective domains.

In both previous cases, it is pretty clear how the DSL is going to look like; discussions are about details, notation, how to formalize things, viewpoints, partitioning and the like (note that those things can be pretty non-trivial, too!).

However, in the remaining third case, however, we are not so lucky. If no domain knowledge is easily available, we have to do an actual domain analysis, digging our way through requirements, stakeholder "war stories" and existing applications. Co-evolving language and concepts (see below) is a successful technique especially in this case.

For your first DSL, try to catch case one or two. Ideally, start with case one, since the people who build the DSLs and supporting tools are often the same ones as the domain experts — software architects and developers.

### 2.1.2 Iterative Development

Some people use DSLs as an excuse to do waterfall again. They spend months and months developing languages, tools, and frameworks. Needless to say, this is not a very successful approach. You need to iterate when developing the language.

Start by developing some deep understanding of a small part of the domain for which you build the DSL. Then build a little bit of language, build a little bit of generator and develop a small example model to verify what you just did. Ideally, implement all aspects of the language and processor for each new domain requirement before focusing on new requirements.

Especially newbies to DSLs tend to get languages and meta models wrong because they are not used to think meta. You can avoid this pitfall by immediately trying out your new language feature by building an example model and developing a compatible generator.

It is important that the language approaches some kind of stable state over time (Fig. 2.1). As you iterate, you will encounter the following situation: domain experts express requirements that may sound inconsistent. You add all kinds of exceptions and corner cases to the language. Your language grows in size and complexity. After a num-

One of my most successful approaches in this case is to build strawmen: trying to understand something, factor it into some kind of regular structure, and then re-explain that structure back to the stakeholders.

Figure 2.1: Iterating towards a stable language over time

ber of these exceptions and corner cases, ideally the language designer will spot the systematic nature behind these and refactor the language to reflect this deeper understanding of the domain. Language size and complexity is reduced. Over time, the amplitude of these changes in language size and complexity (error bars in Fig. 2.1) should become smaller, and the language size and complexity should approach a stable level (ss in Fig. 2.1).

### 2.1.3 *Co-evolve concepts and language*

In cases where you do a real domain analysis, i.e. when you have to find out which concepts the language shall contain, make sure you evolve the language in real time as you discuss the concepts.

Defining a language requires formalization. It requires becoming very clear — formal! — about the concepts that go into the language. In fact, building the language, because of the need for formalization, helps you become clear about the concepts in the first place. Language construction acts as a catalyst for understanding the domain! I recommend actually building a language in real time as you analyze your domain.

To make this feasible, your DSL tool needs to be lightweight enough so support language evolution during domain analysis workshops. Turnaround time should be minimal to avoid overhead.

### 2.1.4 *Let people do what they are good at*

DSLs offers a chance to let everybody do what they are good at. There are several clearly defined roles, or tasks, that need to be done. Let met point out two, specifically.

Experts in a specific target technology can dig deep into the details of how to efficiently implement, configure and operate that technology. They can spend a lot of time testing, digging and tuning. Once they found out what works best, they can put their knowledge into generator templates, efficiently spreading the knowledge across the team. For the latter task, they will collaborate with generator experts and language designer — our second example role.

The language designer works with domain experts to define abstractions, notations and constraints to accurately capture domain knowledge. The language designer also works with the architect and the platform experts in defining code generators or interpreters. For the role of the language designer, be aware that there needs to be some kind of predisposition in the people who do it: not everybody is good at "thinking meta", some people are simply more skewed towards concrete work. Make sure you use "meta people" to do the "meta work".

There's also a flip side here: you have to make sure you actually do have people on your team who are good at language design, know

about the domain and understand target platforms. Otherwise the MD\* approach will not deliver on its promises.

### 2.1.5 *Domain Users vs. Domain Experts*

When building business DSLs, people from the domain can play two different roles. They can participate in the domain analysis and the definition of the DSL itself. On the other hand, they can use the DSL to express specific domain knowledge.

It is useful to distinguish these two roles explicitly. The first role (language definition) must be filled by a domain expert. These are people who have typically been working in the domain for a long time, maybe in different roles, who have a deep understanding of the relevant concepts and they are able to express them precisely, and maybe formally.

The second group of people are the domain users. They are of course familiar with the domain, but they are typically not as experienced as the domain experts

This distinction is relevant because you typically work with the domain experts when defining the language, but you want the domain users to actually work with the language. If the experts are too far ahead of the users, the users might not be able to "follow" along, and you will not be able to roll out the language to the actual target audience.

Hence, make sure that when defining the language, you actually cross-check with real domain users whether they are able to work with the language.

### 2.1.6 *DSL as a Product*

The language, constraints, interpreters and generators are usually developed by one (smaller) group of people and used by another (larger) group of people. To make this work, consider the metaware a product developed by one group for use by another. Make sure there's a well defined release schedule, development happens in short increments, requirements and issues are reported and tracked, errors are fixed reasonably quickly, there is ample documentation (examples, examples, examples!) and there's support staff available to help with problems and the unavoidable learning curve. These things are critical for acceptance.

A specific best practice is to exchange people: from time to time, make application developers part of the generator team to appreciate the challenges of "meta", and make meta people participate in actual application development to make sure they understand if and how their metaware suits the people who do the real application development.

### 2.1.7 *Documentation is still necessary*

Building DSLs and model processors is not enough to make the approach successful. You have to communicate to the users how the DSL and the processors work. Specifically, here's what you have to document: the language structure and syntax, how to use the editors and the generators, how and where to write manual code and how to integrate it as well as platform/framework decisions (if applicable).

Please keep in mind that there are other media than paper. Screen-casts, videos that show flipchart discussions, or even a regular podcast that talks about how the tools change are good choices, too.

Also keep in mind that hardly anybody reads reference documentation. If you want to be successful, make sure the majority of your documentation is example-driven or task-based.

## 2.2 *Using DSLs*

### 2.2.1 *Reviews*

A DSL limits the user's freedom in some respect: they can only express things that are within the limits of DSLs. Specifically, low-level implementation decisions are not under a DSL user's control because they are handled by the model generator or interpreter.

However, even with the nicest DSL, users can still make mistakes, the DSL users can still misuse the DSL (the more expressive the DSL, the bigger this risk). So, as part of your development process, make sure you do regular model reviews. This is critical especially to the adoption phase when people are still learning the language and the overall approach.

Reviews are easier on DSL level than on code level. Since DSL programs are more concise than their equivalent specification in GPL code, reviews become more efficient.

If you notice recurring mistakes, things that people do in a "wrong" way regularly, you can either add a constraint check that detects the problem automatically, or (maybe even better) consider this as input to your language designers: maybe what the users expect is actually correct, and the language needs to be adapted.

### 2.2.2 *Compatible Organization*

Done right, MD\* requires a lot of cross-project work. In many settings the same metaware will be used in several projects or contexts. While this is of course a big plus, it also requires, that the organization is able to organize, staff, schedule and pay for cross-cutting work. A strictly

project-focused organization has a very hard time finding resources for these kinds of activities. MD\* is very hard to do effectively in such environments.

Make sure that the organizational structure, and the way project cost is handled, is compatible with cross-cutting activities. You might want to take a look at the Open Source communities to get inspirations of how to do this.

### 2.2.3 *Domain Users Programming?*

Domain users aren't programmers. But they are still able to formally and precisely describe domain knowledge. Can they actually do this alone?

In many domains, usually those that have a scientific or mathematical touch, they can. In other domains you might want to shoot for a somewhat lesser goal. Instead of expecting domain users and experts to independently specify domain knowledge using a DSL, you might want to pair a developer and a domain expert. The developer can help the domain expert to be precise enough to "feed" the DSL. Because the notation is free of implementation clutter, the domain expert feels much more at home than when staring at GPL source code.

Initially, you might even want to reduce your aspirations to the point where the developer does the DSL coding based on discussions with domain users, but then showing them the resulting model and asking confirming or disproving questions about it. Putting knowledge into formal models helps you point out decisions that need to be made, or language extensions that might be necessary.

If you're not able to teach a business domain DSL to the domain users, it might not necessarily be the domain users' fault. Maybe your language isn't really suitable to the domain. If you encounter this problem, take it as a warning sign and take a close look at your language.

Executing the program, by generating code or running some kind simulator can also help domain users understand better what has been expressed with the DSL.

## 2.3 *Discussion*

### 2.3.1 *Related Work*

Diomidis Spinellis discusses a set of design patterns for DSLs <sup>(1)</sup>. Some of them relate directly to our work: the *Piggypack* pattern describes DSLs that are embedded in a GPL, and the DSL constructs are mapped to GPL constructs for execution. The *Pipeline* pattern addresses the step-wise transformation of higher D programs into lower D programs, which are subsequently translated further. He also defines *Language Extension* to mean that a language has additional fea-

**TODO:** Move this to somewhere where it fits better?

<sup>1</sup> D. Spinellis. Notable design patterns for domain-specific languages. *jss*, 56(1):91–99, 2001

tures compared to its base language, *Language Specialization* removing concepts from a base language. The rest of his paper looks at common use cases for DSLs and DSL implementation techniques. Our work is different in that it aims at a much more complete coverage of the design dimensions, and provides a conceptual framework (the domain hierarchy and composition) to systematically describe DSLs.

Mernik, Heering and Sloane's paper on How and When to Build a DSL <sup>2</sup> provides a comprehensively broad, but relatively shallow overview over the DSL space. It provides patterns that describe the decision process that leads to building DSLs, then connects to some of the design patterns from Spinellis' paper, and finally delves down into actual implementation approaches. The paper also looks at a couple of supporting tools. The strongest aspect of this work is the huge set of industry examples. Our work is more restricted in that it covers only DSL design and not all the decision process involved in DSL development. We also provide much more detail on the core aspects of language design.

Just like in our paper, Zdun and Mark Strembeck <sup>(3)</sup> generalize from a set of DSLs of different sizes, contexts and target platforms. However, instead of focusing on the design of the languages, they focus on the activities involved in building the DSLs, leading to a tailorable DSL engineering process.

In their Worst Practices for Domain-Specific Modeling <sup>4</sup>, Kelly and Pohjonen discuss recurring problems in the implementation of graphical DSLs. The worst practices are based on actual projects, mostly from Metacase customers. Many of the bad practices are not directly relevant to designing (textual) external DSLs, but help in getting a DSL-based development project set up well: *Analysis Paralysis* refers to "Wanting the language to be theoretically complete, with its implementation assured" — i.e. not enough pragmatism and iteration during the design process. *Lack of Domain Understanding* addresses the problem of "Insufficiently understanding the problem or solution domains". *3GL: Visual Programming* refers to the pitfall of "Duplicating the concepts and semantics of traditional programming languages" in the DSL.

Language modularization, composition and extension is an important aspect of DSL design as we describe it in this paper. While building single external DSLs is a pretty well understood and documented topic (as explained in Terence Parr's book <sup>5</sup> and the user guides to the tools mentioned in this paper), modularization, composition and extension of languages and IDEs are still an area of active research. For example, KHEPERA <sup>6</sup> is a system for progressively translating DSLs down along the D hierarchy. OpenJava <sup>7</sup> and the Java Syntactic Extender <sup>8</sup> are macro systems for Java that support the incremental exten-

sion of Java with additional syntax. The extensions are translated back to the Java idioms from which they abstract. In <sup>9</sup>, Bravenboer, Dolstra and Visser discuss an approach for embedding of arbitrary guest languages into arbitrary host languages. Xoc <sup>10</sup> and the Modular Embedded DSL <sup>11</sup> provide similar functionality for C. MontiCore <sup>12</sup> supports the development of modular languages, where binary composability, so no language sources such as grammars are required for composition. Finally, Hemel and Visser describe PIL <sup>13</sup>, an intermediate language intended as to be used as a reusable transformation backend for DSLs - DSLs are transformed to PIL, reusing a set of existing reusable PIL backend for several target languages.
